CLINICAL LECTURE

ON CASES OF PAINFUL AFFECTION OF THE FOOT.

BY THOMAS G. MORTON, M.D.,

One of the Surgeons to the Pennsylvania Hospital; also Surgeon to the Philadelphia, Orthopædic, and Jewish Hospitals; Emeritus Surgeon to the Wills Ophthalmic Hospital; Consulting Surgeon to the Woman's Hospital and to the Pennsylvania Institution for the Instruction of the Blind, etc.

SOME ten years ago I published an account of a "Peculiar and Painful Affection of the Fourth Metatarso-Phalangeal Articulation," and reported a number of cases of an affection of the foot involving the proximal joint of the fourth toe.* I then stated that I considered this malady of sufficient importance to be brought to the notice of the profession generally, especially as it unquestionably had not been recognized before that time.

My attention was first directed to this peculiar affection in 1870. After a careful study of a case which came under my observation at that time, I became convinced that I had an unusual condition to deal with. In this instance the symptoms were so clearly marked, and my patient, who was an intelligent woman, gave such a positive account of her painful malady, that I was satisfied that I had to treat a condition which had not previously been described by systematic writers or in the medical journals, at least as far as I was aware. Since that time I have had such a number of these cases coming under my observation, and have learned of so many others in the hands of medical friends, that I have no hesitation in saying that the disease is a very common one, and that even up to the present time it has not been recognized by the profession as it should be.

This neglect or apparent indifference on the part of the profession may perhaps be due to the fact that the foot, to most persons, is not a very interesting portion of the human frame, so that, as a rule, a sufferer with any painful condition of the feet presenting no conspicuous abnormality is usually referred to the chiropodist, who is only able to cope with the simplest affections of this important region. Too often it happens that the general practitioner dismisses the cases which I shall describe as beneath his consideration: the pain is looked upon as a form of gout or rheumatism, even where this is not sustained by the family or personal history of the patient, and the case is sent away with directions to get less fashionable shoes, or with some other trifling recommendation, no diagnosis having been made. Consequently, the sufferer remains unrelieved, and in time settles down to the conviction that he is the victim of some constitutional or incurable malady; and so he goes on, suffering periodical attacks of almost intolerable agony with a disease which, if properly understood, could be readily and permanently cured.

This painful joint-disease, which is strictly local, may be of a mild or a severe type. Cases of the mild form of the affection, which are said to be bearable, may develop into the severe form. In them occasional attacks of pain are followed by periods of complete immunity, the neuralgia coming back again from time to time. The cases of the severer form are usually so from the commencement: they frequently result from a sprain or twist of the anterior portion of the foot or from undue pressure of a shoe. Occasionally the neuralgia has appeared simultaneously in both feet; in such cases it may be dependent in part upon ill-fitting shoes: indeed, in two cases I have seen the disease was undoubtedly induced by ill-fitting ready-made shoes, and in one case the pain came on at once in both feet from a similar cause.

In my first account of this disease I only mentioned pain occurring in the metatarso-phalangeal joint of the fourth toe; but I have since seen instances in which the corresponding joint of the third toe was involved. Dr. Erskine Mason, of New York, has published the report of a case of metatarso-phalangeal neuralgia which he successfully treated by excision of the joint of the second toe.†

I have made some extended inquiries among the larger retail shoe-dealers, in order to find out if their attention had ever been called to this painful condition of the foot by their customers. I learned that this peculiar condition has not only

* American Journal of the Medical Sciences, January, 1876.

† American Journal of the Medical Sciences, Oct. 1877.

been frequently recognized by them, but that it is also considered to be quite common. Almost every intelligent shoe-retailer has seen a number of persons to whom this disease has been a source of frequent suffering, and who believe their malady to be beyond relief by medical art. Indeed, it would seem that in some of the most severe of the cases it has been found impossible to obtain the serious consideration of their condition by their medical attendants.

The history given by the patient will generally be like the following, which should be sufficient to lead to a correct idea of the trouble. One of my patients wrote as follows:

"During the summer of 1868, while travelling in Switzerland, I made a pedestrian tour to the valley of the Faulhorn Mountain, and when descending a steep ravine I trod upon quite a large stone, which rolled from under my foot, causing me to slip, and throwing my entire weight upon the forward foot: though not falling, I found my right foot injured. The pain was intense and accompanied by fainting sensations. With considerable difficulty I reached the valley of the Grindelwald, where for hours I endured great suffering. After this I found it impossible to wear a shoe even for a few moments, the least pressure inducing an attack of severe pain. At no time did the foot or toe swell or present any evidence of having been injured. During the succeeding five years the foot was never entirely free from pain: often my suffering has been very severe, coming on in paroxysms. I have been only able to wear a very large shoe, and only for a limited space of time, frequently being obliged to remove it to relieve the foot. Much of the time I have gone without any covering except a stocking, and even at night have suffered intensely: slight pressure of the finger on the tender spot causes the same sensation as wearing a shoe. During the past year or so I have walked but little, and consequently have suffered much less."

In this case a twisting of the foot was followed by acute pain, which was succeeded by permanent local sensitiveness or tenderness and neuralgia, brought on by pressure of the shoe or stocking, and sometimes without any known cause. The pain was always referred to the metatarso-phalangeal joint of the fourth toe, but during the severe paroxysms it extended up the limb as far as the knee and hip. On examination there was found neither redness nor swelling of the foot. The head of the fourth metatarsal bone, with the adjoining phalangeal base, was exceedingly sensitive, and pain was caused by the slightest pressure. In this case, at my suggestion, a deep excavation was made in the sole of the shoe which she wore, which was sufficiently broad to permit the affected joint to be as free as possible from pressure, and local anodyne applications were made, but the patient obtained no relief. I then considered the propriety of excision of the joint; but the patient was threatened with pulmonary disease and not in a condition to undergo any treatment that would confine her indoors. In June, 1873, I again saw this patient, on this occasion in consultation with Dr. Ellwood Wilson. There had been no improvement in the affected joint from treatment during this period. A short time before visiting this patient, however, in the same year, I had had under my care a similar case which I had successfully treated by excision of the painful joint, but neither Dr. Wilson nor I deemed it advisable to perform this operation upon this patient, on account of her impaired physical condition.

In the following case an operation was successfully performed.

In March, 1873, I was asked to see Miss H. S., aged 26 years, who, while in Europe four years before, had injured her right foot by stepping upon a small stone. She said that she had at once experienced intense pain, which was soon followed by slight swelling and redness. From the date of the injury localized pain in the foot continued, especially while wearing a shoe. The pain was referred to the head of the fourth metatarsal bone. There was constant distress in the part, often of a sickening character. After wearing a shoe, pain came on with great intensity. At such times the shoe had to be instantly removed, the least delay causing a paroxysm of great suffering. The boot or shoe had to be removed so often that a slipper was substituted. A marked lameness was induced by the patient's endeavor to spare the foot in walking. The pain was confined to the joint of the fourth metatarsal bone with the base of the associated phalanx. Pressure in this region or rolling the fourth and fifth toes upon each other caused violent pain, which extended up the limb. It was severe when pressure was made upon the base of the first phalanx of the fourth toe, which could be prominently felt between the third and fifth toes. Rest, anodynes, and other applications failed to relieve this patient. Dr. William Hunt, who had frequently seen this case in consultation, agreed with me in advising excision of the joint.

On March 22, 1873, after etherization, an incision two inches in length was made on the outer edge of the extensor tendon of the fourth toe; the metatarso-phalangeal articulation was then opened, and a portion of the shaft of the metatarsal bone, with the head of the bone, was excised; likewise a quarter of an inch of the shaft of the phalanx. The wound soon closed; the toe was shortened half an inch by the operation. The patient has since visited Europe on two occasions, and has remained in perfect health, and has been able to wear any form of shoe.

This, and the following cases, may be taken as types of the disease, of which I reported thirteen cases in my first paper, and have seen more than twice as many since, and several have been reported in the medical journals.

The following cases are such typical illustrations of the affection that I abstract them from a previous article upon this subject.*

Dr. M. W. Alison, of Hagerstown, Maryland, called on me in the spring of 1875, seeking relief from neuralgia in his right foot, which had existed for years and was gradually getting worse, and stated that he was willing and ready to submit even to amputation of the leg. He gave the following history:

"About six years ago I experienced an unpleasant painful sensation in my right foot, which possibly originated in a strain: the pain was first observed in the fourth metatarso-phalangeal region; in the course of a fortnight it was followed by most violent pain, which was simply unbearable and so severe that it terminated in a convulsion. A painful condition of the parts followed, and with the least provocation (wearing a shoe or boot), sometimes without known cause, paroxysms of intense pain returned at various intervals, lasting from one to forty-eight hours. The pain, with one or two exceptions, has been confined entirely to the section of the foot indicated. My suffering has been beyond all comprehension: very often I have been compelled to jump from my buggy or stop while walking, remove my boot, which has always been of ample size, apply ligatures to the limb or foot, use hypodermic injections of morphia, frictions, or call upon some one to assist me by standing on the foot. This affliction has been the burden of my life, and this burden has been increased after consulting many eminent medical men, who gave me no satisfaction as to the nature of the disease, nor even suggested a hope of relief. My health otherwise has been uniformly good. I am satisfied the cases you have had are similar to my own save in the intensity of my sufferings, and I shall gladly submit to the operation you have suggested."

Operation.—June 15 I made an incision on the upper side of the fourth metatarsal bone, the shaft of which was divided half an inch beyond the head of the bone; the base of the first phalanx was also removed; the toe was then found to be so isolated that it was removed; the adjacent soft parts were dissected away to insure the excision of the surrounding nerve. On the third day Dr. Alison left the city, and subsequently wrote, "Am happy to report all right; have not experienced any pain whatever, and am feeling better than I have for years, and feel assured that the operation will give me permanent relief."

In April, 1872, Mr. W. K. M., of Rome, Noble County, Indiana, wrote me as follows: "I am a carpenter, and have been a hard-laboring man all my life. In 1866 I was suddenly seized with pain in the joint of the fourth toe of my right foot; at times was obliged to pull off my boot and sock, which gave me relief; many times I would wear my boot without my sock; at times the toe would puff up and become numb. In 1867 it was worse; I wore a larger boot, but was often very lame. In 1870 I had to use a cane, but kept at work until two years later, when I was unfit for business, for the pain was nearly constant.

"The disease was called rheumatism and gout; rest and quiet proved the best remedy for the time; the neuralgia then extended to the back of my heel, and was an aching, heavy, dead pain, so that I could not even bear the weight of the bedclothes."

In December, 1876, this patient came to Philadelphia. An examination showed the usual pain on pressure; the foot was normal in appearance. As there was some tenderness also in the same joint of the third toe, I excised the joints of the third and fourth toes.

Some months later Mr. M. wrote me, "My foot was tender for some time after I came home; but at the present time it is well. I have no pain, and can safely say that it is a permanent cure, and feel satisfied that the operation has saved my life." Four years later this patient reported himself as perfectly well and no lameness, and that he had worked steadily since his return.

Dr. Thomas, of Savannah, Georgia, also wrote me in 1876, reporting a case which had come under his notice: "I think your article throws some light on a case which has been under my advice for several years, and I have looked in vain through some of the surgical authorities for guidance. The patient is a young lady, with every comfort around her. For the past three or four years she has suffered with a severe pain in the fourth

* Surgery in the Pennsylvania Hospital, article entitled "Painful Affection of the Foot." Philadelphia, 1880. P. 109.

metatarso-phalangeal articulation of the left foot, sometimes brought on by long walks, and at other times without any immediate provoking cause. She does not know that she has ever hurt the part, though possibly has sprained it, but not enough to have noticed it. There has never been any swelling or redness perceptible, but always more or less sensitiveness to pressure or the touch. The joint, when handled, appears to be too loose; otherwise no abnormal indication save the pain.

"I have tried many things in the way of treatment, but all without proper success. She has applied tincture of iodine, belladonna plaster, capsicum plaster, etc. There are times when she thinks that a comfortable-fitting shoe feels better than a looser one. My impression is that this neuralgia, or whatever it may be called, is more common than we would at first think, and the profession may be grateful to you for the article mentioned."

The following graphic description is from a medical friend who has himself suffered from the more severe form of this neuralgia:

"PHILADELPHIA, January 1, 1877.

"I have read with pleasure and profit your paper on a 'Peculiar and Painful Affection of the Foot.' Thinking it might be interesting to you, I send you an account of my own case.

"I have suffered intensely at intervals from this affection for many years, and in all this time have never found medical man or layman who understood what I meant when I complained of it or alluded to it. It has been pronounced by surgeons who have examined my foot to be a subluxation or a malformation of the articular surface of the first phalanx of the fourth toe, where it articulates with the fourth metatarsal bone, the concavity not being sufficiently concave. This I have long been convinced is an error. By other eminent authorities I have been conveniently 'pooh-pooh-ed.' By persons out of the medical profession I have been in my agony comforted by an 'Oh, tight boots.' I had at last despaired of making anybody understand my ailment, summoned all my patience, and suffered in silence.

"My own sensations have convinced me that the pain is caused by pressure upon a nerve, but what pressed upon the nerve I was unable to tell. The immediate necessity of removing the boot and the relief afforded by manipulating the foot in a manner learned by experience pointed to a dislocation; but the reduction of the displacement was never sufficiently sudden and marked to confirm the belief that there had been a dislocation.

"Now, after living for more than half a century, practised my profession for over thirty years, and suffered half my life with an affection not understood and ranked with a disease so trifling as a corn, I find myself enlightened and the mystery cleared up by your valuable paper on the subject.

"The first paroxysm occurred in my boyhood, and was produced by tight lacing of skate-straps. On unbuckling the straps, the 'cramp,' as I called it, was at first soon relieved and thought nothing of; but a continuance of this system of squeezing by tight straps and tight boots, and riding for hours on horseback with the flexors of the leg and foot in violent action and the toes turned in, the attacks became more frequent, more painful, and the abnormal condition of the parts became chronic. These were in my case undoubtedly the causes predisposing. The causes determining the accession of a paroxysm are the wearing of a badly-fitting boot, especially if the sole be narrow; a long and fatiguing walk, particularly on a hot day over a hot pavement; a long ride on horseback; a wet boot sticking to the sock; a wet sock sticking to the toes; long-continued flexion of the knee-joint, as in a railroad-car, carriage, or lecture-room; treading on an uneven surface, as a cobblestone pavement; and, should the nervous system be depressed from any cause, these exciting causes will act more powerfully.

"The symptoms of an attack in my case are most intense pain, 'cutting to the heart,' sickening, a feeling that it is unendurable, faintness, cold sweat, total incapacity for the time of directing the mind or will to any other subject, a horrible increase of torture on the use of the boot-jack; and all this with no redness, no swelling, no abrasion of the skin, no callosity, no visible displacement of bones, at least after removal of the boot.

"The suddenness of the attack is noteworthy. I have been obliged to drop everything and remove my boot, sometimes in company, sometimes in my carriage. I have even been obliged to sit down on the curb-stone and remove the boot. I have dismounted from my horse and sent home for slippers before I could proceed. I have tied my horse to a tree and lain on the ground, unable to ride farther.

"I have spoken of a tight boot and of removing the boot, but I have had tight boots which were great favorites, because they would not 'let my toe out of joint.'

"The remedies from which I have obtained relief are removal of the boot and then manipulating the toes, straightening them out. When inconvenient to take off the boot, I have found that grasping the foot tightly round the metatarsal region will answer; and I have sometimes worn a circlet of india-rubber band, binding the foot round the instep. Putting on a dry boot and dry stocking is of great benefit, and the boot should be well sprinkled with powdered soapstone before putting it on. Frequently an attack has been relieved completely without other means than rest and a cup of strong tea."

These clinical notes of cases might be greatly extended, but the above will suffice to show the disabling and painful character of this affection and the propriety of the means adopted for its relief.*

Painful affections of the feet have long been known as a cause of disability among soldiers, but, so far as I can learn, the peculiar disorder under consideration has not been described as a cause of tender feet.

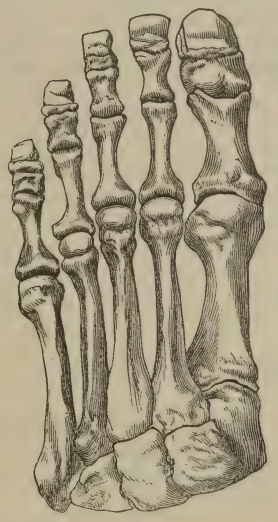
In order to satisfy my mind, I addressed a query upon this point to Surgeon J. S. Billings, of the Surgeon-General's Office, U.S.A., Washington, who replied under date of September 4, 1886, as follows: "I do not think there are any records of the special conditions which you describe as occurring among soldiers. Cases of excuse from duty on account of painful feet are occasionally reported, but these seem to be mostly of a temporary character, and are not described with sufficient fulness to make it certain what part of the foot is affected."

With regard to the etiology of this disease, I think that the explanation I have already given in a former paper has been supported by subsequent observation.

The occurrence of neuralgia may be understood by a reference to the anatomy of the parts. The metatarso-phalangeal joints of the first, second, and third toes are found on almost a direct line with each other, while the head of the fourth metatarsal is from one-eighth to one-fourth of an inch behind the head of the third, and the head of the fifth is from three-eighths to half an inch behind the head of the fourth: the joint of the third, therefore, is slightly in advance of the joint of the fourth, and the joint of the fifth is considerably behind the joint of the fourth.

The fifth metatarsal joint is so much posterior to the fourth that the base of the first phalanx of the little toe is brought on a line with the head and neck of the fourth metatarsal, the head of the fifth metatarsal being opposed to the neck of the fourth (see illustration).

On account of the character of the peculiar tarsal articulation, there is very slight lateral motion in the first three metatarsal bones. The fourth has greater mobility, the fifth still more than the fourth, and in this respect it resembles the fifth metacarpal. Lateral pressure brings the head of the fifth metatarsal and the phalanx of the little toe into direct contact



with the *head and neck of the fourth metatarsal*, and to some extent the extremity of the fifth metatarsal rolls above and under the fourth metatarsal.

The mechanism of the affection now becomes apparent when we consider the nerve-supply of the parts. The branches of the external plantar nerve are fully distributed to the little toe and to the outer side of the fourth; there are also numerous branches of this nerve deeply lodged in between these toes, and they are liable not only to be unduly compressed, but pinched by a sudden twist of the anterior part of the foot. Any foot-movement which suddenly may displace the toes, when confined in a shoe, may induce an attack of this neuralgia. In some cases no abnormality or other specific cause for the disease has been detected.

The question of treatment may be dismissed in a few words. In acute cases of this disease, where it has evidently been induced by an injury, the treatment should be by local depletion, anodyne applications, and rest, and, as in those less severe cases which do not seem to demand operative treatment, a suitable, broad-soled shoe should be worn, which should lace up in front.

The greatest comfort and often entire relief is afforded by the use of a narrow, fine flannel bandage, which should cover

* Feeling convinced that this is a comparatively common affection, Dr. Morton would be obliged to his readers if they will send him brief clinical notes of cases coming under their observation.

the anterior part of the foot moderately firmly, so as to give absolute steadiness to all the toes, and tight enough to prevent any rolling or movement of the joints or toes upon each other. In very many cases this simple treatment has, with a properly-constructed shoe, given entire comfort. Even in the most severe cases this treatment should be fairly tried before an operation is decided upon.

In some cases, however, no treatment except excision of the irritable part will be of any service, and the excision of the joint of the toe, which is readily performed and quickly recovered from, will insure a complete and permanently good result.

ORIGINAL COMMUNICATIONS.

CHRONIC BRIGHT'S DISEASE OF THE KIDNEYS.

BY J. H. PRICE, M.D.,
Elmira, New York.

AN eminent authority says, "Kidney-disease is probably the most frequent cause of death in this climate,—in adults, a more common cause of death than consumption."

That the number of deaths from chronic Bright's disease is yearly increasing may be readily ascertained by a study of the vital statistics of the tenth United States census.

It is nearly one-third more frequent in males than in females, and this excess obtains at every age. Millard "thinks the explanation of this is to be found mainly in the fact that the male sex undergoes more exposure to unfavorable atmospheric influences, and that the same sex is more liable to renal and urethral inflammations, as well as calculus." The mortality from chronic Bright's disease shows a progressive increase from childhood to nearly the age of sixty; during the next fifteen years the mortality continues steady at a somewhat lower rate.

The consequences of chronic Bright's disease may be best understood by remembering what the functions of the kidneys are: viz., primarily to maintain the blood at a proper specific gravity by removing excess of water and excess of salts from it, as well as special nitrogenous excreta; the duty of the kidney is to regulate the quantity as well as the quality of the blood. Should these functions be inadequately performed through harmful external or internal influences, we will have retention and accumulation of excreta in the blood to interfere with the assimilative nutritive changes, making their way out of the body by the intestines, skin, or, later, provoke inflammatory changes. While there are at least three well-recognized forms of chronic Bright's disease, each presenting considerable diversity as to cause, modes of origin, and symptoms, yet they have points of resemblance so strong and so numerous that they form an easily-recognized clinical group. This resemblance is due in a great measure to the fact that the structural changes in the kidneys, however varied, produce the same ultimate results,—namely, impoverishment of the blood from loss of albumen, with retention of effete matters of the urine,—and the more prominent symptoms of chronic Bright's disease arise from the changed composition of the blood and changes in the vascular system,—namely, thickened arteries, obliterated capillaries, and consequent interference with glands.

The symptoms in chronic Bright's disease are often influenced by a family tendency. Patients who come from a dyspeptic family complain of gastric disturbances, as nausea and vomiting; those who come from a phthisical family first present some pulmonary difficulty, as asthma, bronchitis, or frequent and very severe coryza; others have a tendency to nervous complaints, and will complain first of severe and persistent headache and results. These facts should lead us to look to chronic Bright's disease a good deal more than to almost any other chronic disease for the cause of obscure affections, and it is for this reason I make it a routine habit to examine the urine in every case of chronic disease coming under my care. In chronic Bright's disease any one of the principal organs of the body may be affected. Apoplexy, as is well known, is a serious and frequent accident, especially in the aged. It has been shown by statistics that three-fourths of the cases of apoplexy are due to chronic Bright's disease. If this fact were early recognized, much might be done to prevent this terrible accident. Millard, relative to this point, says, "In a numerous class of cases, nephritis exists in persons of good constitutions without assuming such proportions as to produce noticeable symptoms or seeming to deteriorate the health, and without being accompanied by the

presence of albumen. It is this class of cases, however, which frequently is accompanied by atheroma of the arteries, leading to apoplexy, without the ultimate cause of death ever having been suspected."

Chronic parenchymatous nephritis, chronic interstitial nephritis, and the waxy or amyloid kidney are the three best-known forms of chronic Bright's disease. These forms may be blended or combined, chronic parenchymatous nephritis in the vast majority of cases being primarily chronic or subacute; chronic interstitial nephritis, though said to have an acute origin in exceptional cases, is very rarely recognized as such, and may be practically considered primarily chronic; the waxy or amyloid kidney, as its name indicates, is always a chronic disease. By far the most prolific causes in common, observed both in chronic parenchymatous and chronic interstitial nephritis, are atmospheric conditions, damp, cold, unfavorable climate, check of perspiration, etc.; other causes, as malarious poisoning, syphilis, scrofula, alcoholism (from this cause more often secondary to changes in the liver than direct), lithæmia, pregnancy, heredity, cystitis, gout, lead-poisoning, and valvular disease of the heart coming next in frequency. The waxy or amyloid kidney may be consequent upon chronic parenchymatous nephritis or some dyscrasia, as syphilis, chronic abscesses, prolonged suppuration, Pott's disease, caries, etc.

The symptoms of chronic parenchymatous nephritis are increased frequency of micturition, the quantity of urine, however, being below normal; the urine, which amounts in health to about fifty ounces in twenty-four hours, is reduced in quantity to twelve or sixteen ounces, the amount of urea being proportionately small; the specific gravity of the urine is usually higher than normal; the urine is always albuminous. The albumen, which in healthy blood is sixty-five in one thousand, in this disease is reduced to about sixteen parts. About the same time with the increased frequency of urination a certain amount of lassitude is developed; the patient experiences a loss of energy and physical strength. These symptoms are frequently accompanied by some renal pains which are often mistaken for rheumatic pains; persistent and unmanageable headaches and dyspeptic symptoms are common; pallor of the complexion, presenting a peculiar ashy whiteness, is often noticed. These conditions do not fail to be followed soon by the tell-tale œdema of the eyelids or of the feet; nausea usually supervenes at an early stage; where the disease is further advanced there is emaciation, often marked anasarca, dropsy of the cavities, and also œdema of the mucous membranes, lungs, and intestines; in the advanced stages the dropsical effusions take the place of the urinary secretion. It is in this form of nephritis that dropsical affections are most frequent, occurring in most cases, and assuming their most formidable aspects, sometimes producing sloughing of the cellular tissues. An important fact concerning the existence of albumen in this form of nephritis is that it is never absent, and is often present in much larger quantities than in any other form. The amount of uric acid excreted does not vary much from the normal; urinary casts are always to be found, the granular cast being indicative of this form of nephritis and usually predominating; hyaline casts, and in certain conditions of the kidneys waxy and fatty casts, may usually be found. When there is pyelitis or ulcerative destruction of the kidneys, we often find shreds of connective tissue; pus-corpuscles and epithelia from the tube-system are always present, with a few blood-corpuscles. The above phenomena in the urine usually denote chronic parenchymatous nephritis, with acute recurrence.

Upon the subject of chronic interstitial nephritis, Millard says, "There is no organic disease which lingers so slowly in its apparent development as this form of nephritis: apparently even good health may be enjoyed after its development; uræmic headaches may even occur without albumen ever being found in the urine." Its early progress is often remarkably insidious, and readily escapes recognition, one of the first symptoms noticed perhaps being a gradually-increasing loss of strength; severe and persistent headaches, loss of appetite, nausea, bilious derangements, flatulence, diarrhœa, etc., being next in frequency; disturbances of vision, as seeing bright or dark specks or a haziness before the eyes, and a peculiar stare is sometimes noticed, among other symptoms; an unhealthy look is often developed, sometimes anæmic and usually pallid; the features appear blighted, and the hair may change its natural color to the

premature hue of old age; a frequent desire to urinate, the urine being passed in considerable quantities, soon becomes noticeable (the patient often is obliged to rise several times in the night to urinate); the urine is generally pale, clear, often soapy-looking; the specific gravity is usually low (1000 to 1014). Deep-seated violent pains in the limbs are not uncommon; bronchitis, asthma, pericarditis, and pneumonia are frequent complications in chronic interstitial nephritis; disturbances of the nervous system are frequent; the most amiable and sanguine dispositions may become morbidly depressed, peevish, suspicious, and impatient; sometimes mania, with suicidal tendencies, is developed; later on, intense itching over the whole body, and a urinous smell.

Coma is more likely to occur in this form of Bright's disease than convulsions, and is of serious import. One of the most constant and characteristic lesions of chronic interstitial nephritis is hypertrophy of the left ventricle, generally without valvular lesion: that this exists almost always in advanced stages is generally conceded.

Another sign which almost never is absent in advanced stages is a feeling of a uniform thickness of the arteries, like a smooth wire. It differs from senile thickening in that the latter is not uniform, but feels like a string of beads. The pulse is incompressible,—that is, requires a great amount of pressure to stop it. Hemorrhagic attacks are more common in this than in any other form of nephritis: they take place from the nose, from the stomach, and within the cranial cavity. Apoplexy as a cause of death in chronic interstitial nephritis is very common; dropsy does not occur, though there is often œdema of the eyelids and sometimes slight œdema of the feet; œdema of the lungs often brings about a fatal termination. "In regard to the presence of casts and albumen, it may be said that in the progress of a particular case nearly all forms of casts may be encountered, but a preponderance of any one of them affords an indication of the exact state of the kidneys: the apparent absence of casts from albuminous urine is no absolute proof of the non-existence of renal degeneration."

Chronic interstitial nephritis is not to be detected by the familiar and easy plan of testing for albumen alone. It has been shown by Millard that "this form of chronic nephritis may for a long time exist, and even produce cirrhosis, without albumen ever existing in this form of nephritis." Bartells says, "Albuminuria is no constant symptom in this affection." In many cases albumen is found in very small quantities in the urine, at irregular intervals, requiring the most delicate chemical tests to demonstrate its presence. Professor W. H. Thompson says, "We may take as a rule that in about one-half the cases of six months' duration albumen will be found in the urine, in the other half it will be absent. Albumen is probably absent in about one-third of the cases from the beginning to the end of the disease." Dr. Millard, who has had an immense experience, says, "The conclusion that nothing is the matter with the kidneys because after several examinations of the urine no albumen is found is sometimes literally a fatal error: yet how numerous are the instances where, after the orthodox one or two chemical examinations, the kidneys are pronounced healthy!" He adds, further, that these false conclusions are not reached, as a rule, by the illiterate and uneducated practitioner exclusively, but by medical men who are considered eminent. To test simply for albumen, and that only once or twice, is often useless. It must be tested repeatedly; the quantity, specific gravity, and chemical peculiarities must be carefully noted; and, *most of all*, the phenomena *disclosed by the microscope* must be considered. Casts are comparatively rare in the urine of these patients, the hyaline variety predominating. Epithelia and oxalate of lime crystals are usually present. Much time and patience are sometimes indispensable to the examination of the urine of chronic interstitial nephritis, as it may vary greatly.

The waxy or amyloid kidney is a disease easy to recognize during life, perhaps more so than either of the other forms of renal disease. Extensive œdema and ascites mark this form; the urine is pale, watery, and passed in large quantities; albumen is sometimes found in the urine in large amounts, also numerous hyaline and fatty casts, the specific gravity being moderate. This form of nephritis is the most dangerous, hopeless, and rapid.

The great leader of the profession in this country, the late elder Dr. Austin

Flint, in a recent paper entitled "The Elements of Prognosis in Bright's Disease," said that in the popular mind the "name 'Bright's disease' at the present time had a prophetic import not unlike that of a verdict of conviction after a trial for life. It was regarded as a hopelessly fatal malady." In considering the elements of prognosis in cases of chronic Bright's disease, he said, "1st, the kidneys must not be damaged beyond a certain degree; 2d, the important organs of the body other than the kidneys must be capable of performing their respective functions satisfactorily; 3d, the laws of health relating to alimentation, exercise, etc., must be observed. Suppose these conditions to be fulfilled and a lesion of the kidneys to exist which diminished their functional activity one-half, and the disease was not progressive; life and health would be compatible with the existence of chronic Bright's disease for an indefinite period." Drs. Janeway, Draper, Delafield, Loomis, and Barker corroborated the conclusions drawn by Dr. Flint. Dr. James Tyson says, "It is a popular error that Bright's disease means death," and that he would rather have Bright's disease than phthisis. Dr. W. H. Thompson says, "If you can get the kidneys to secrete urine of 1025 in specific gravity, and in quantity a pint and a half for the twenty-four hours, you can give a good prognosis." Dr. Millard says, "It is by no means necessary to take a despondent view of the situation because casts, renal epithelia, or albumen are generally found. Other conditions, as the rational symptoms, the constitution of the patient, a decision, if possible, whether the disease is extensive or small in amount, must be considered before prognosis is formed. There are many well-marked cases in which the physician is justified in extending a most favorable and hopefnl vista, if not a cure, at least of practically good health."

These encouraging words from some of the most eminent and best qualified of the profession to speak upon this subject are fraught with significance. My own experience leads me to take a most hopeful view of the outcome of many of these cases under proper care and good treatment. This view is based upon the recovery of a number of apparently hopeless cases occurring in my practice, some of which I give to illustrate this fact. Many of the same remedies and measures of treatment apply equally in the different forms of chronic nephritis: still there are differences required, often of an essential and vital character. We will surely err if we rely solely upon drugs. It will be fortunate if the patient be so situated that he can have the advantage of rest, mentally and bodily. The influence of the latter has been shown to be of the greatest value in diminishing albuminous exudation from the kidneys. Fatiguing exercise must always be avoided. In unfavorable seasons of the year it might be important for the patient to have recourse to a southern climate. Bodily warmth is essential in all seasons of the year. If a patient can be made comfortable at home, I believe that to be the best place for him. The warm room, good nursing, food, etc., to be had at home among friends are of inestimable value in these cases. Fleece-lined or silk undergarments, according to the season, should be worn next to the skin the entire year. I would especially recommend for these patients the "Jaros hygienic underwear:" these garments are light, warm, and delightfully soft. They afford full protection to the body against sudden chilling. Dietetics are of great importance. In chronic parenchymatous nephritis nitrogenous food in proper quantities is beneficial; in chronic interstitial nephritis, the loss of albumen being small, animal food to a great extent should be avoided. In either case, if the patient be of full habit, a purely milk diet will give the best results. I furnish each patient with a diet-table, arranged to meet the special indications in his particular case.

The amount of animal food must depend upon its effect upon the patient's system and condition. Certain alcoholic beverages are sometimes useful, and do much towards stimulating the depressed energies and limiting waste of tissues.

Hot-air or vapor baths often serve a good purpose, and under the advice of a physician may be employed frequently. In advanced cases the use of jaborandi or pilocarpine may take the place of baths. The remedies that I have found most useful in the treatment of these cases are hydrarg. corrosiv. chloride, digitalis, quiniæ bisulph., citrate of caffeine, nitroglycerin, chlor. aurum et sodii, tinct. ferri chlor., and the mixture known as the "four chlorides."

There are many remedies that in special cases are very useful; but those mentioned have in my practice given the best results in the largest number of cases.

Case I. Chronic Intersititial Nephritis without Albuminuria.—C. E., aged 38, farmer, consulted me in March, 1880. Family history good. He had done service during the late war, and contracted chronic diarrhœa and "chills and fever," from which he suffered for several years. For the past two years his health has been miserable; could perform no manual labor whatever; for six months past the slightest exertion brought on terrific asthmatic paroxysms, vertigo, and palpitation of the heart; has severe headaches, insomnia, loss of appetite, constipation, and nausea; looks pale and emaciated. He had noticed swelling of eyelids and feet for some time past. The heart is hypertrophied, but no valvular lesion; pulse 110, with tense, wiry feeling; urine pale and soapy-looking; passes nearly six pints in twenty-four hours; specific gravity 1006; no albumen; hyaline and a few granular casts; kidney-epithelia and oxalate of lime crystals were seen under the microscope.

After three months of active treatment, improvement began, and continued up to the time I pronounced him cured, two years later. He does heavy work upon his farm all the year round, and is at this writing apparently as well as ever he was. During the first year he began to labor he would have an occasional "twist," as he expressed it, with his heart or the asthma. At no time during the progress of the case was albumen found in the urine.

Case II. Chronic Interstitial Nephritis without Albuminuria.—A. S., aged 28, single, waiter-girl, consulted me July, 1883. Family history not known. She had been losing strength and weight for a long time; she is pale, emaciated, and complains of a constant tired feeling, loss of appetite, sick headaches, vertigo, and dimness of vision; her heart troubles her a great deal; she is constipated, and has frequent desire to urinate. An examination revealed an enlarged heart, no valvular lesion, arteries hard and tense. She passes about four pints of urine in twenty-four hours, pale and watery, specific gravity 1010; a few hyaline casts only are seen under the microscope.

After eight weeks' treatment, she began to improve. At the end of the third month, contrary to my advice, she discontinued treatment. In April, 1884, I was called in haste to see her. I then learned that she had continued in fair health until the last of February, since which time she had rapidly grown worse. At the time of my visit she had experienced severe cramps in her abdomen and fallen to the floor in a faint. She had the appearance of being very ill with a fatal disease; but I determined to give her the benefit of active treatment. She rallied, and after weeks of anxiety she began to improve. In October, 1885, I pronounced her cured, and she has continued to enjoy good health since.

Case III. Chronic Parenchymatous Nephritis.—The husband of Mrs. L., aged 32, of Waverly, New York, wrote me in regard to her case in September, 1883. I sent directions how to prepare samples of urine to send to me for examination, also a list of questions, from which I learned the following history of the case. For two years past she had suffered from great lassitude and emaciation, dimness of vision, dull headaches (at times very severe and prostrating), nausea and vomiting, frequent attacks of bronchitis, frequent micturition in small quantities, swelling of the feet and body, much thirst. The urine contained a considerable amount of albumen and granular casts. Her case had been pronounced incurable by two physicians who had been treating her. I immediately put her under treatment. I saw her at intervals of a week for several weeks. At the end of twelve weeks she began to improve. I kept her under observation and treatment for two years, after which time I considered her cured. I saw her last week, and she continues in good health.

I could cite many more such cases ending in recovery; but these will, I hope, sufficiently prove to your minds that we need not necessarily give a gloomy prognosis because the symptoms are grave or because the case has been given up by other physicians; but let our motto ever be "*Nil desperandum.*"

VISITS TO THE FORUM OF THE WHIPPING-POST.

BY G. M. BRADFIELD, M.D., AND THOMAS H. ANDREWS, M.D.

(*Read before the Medical Jurisprudence Society of Philadelphia, and ordered to be printed by resolution of the Society.*)

TO labor through an encyclopædic essay upon the "scourge" would argue a poor appreciation of the honor conferred in inviting us to address you upon our personal observations and impressions of the whipping-post. Nor shall we dwell upon the historical aspects of our subject, merely observing, in passing, that whether in Rome, the symbol of retaliative justice, in Asia Minor, in the shadow of the Pyra-

mids, in Africa, or in the Western hemisphere as the awful adjunct to the dreadful crime of human slavery, wherever and whenever it has existed, the lash degraded the power that used it, and has been shown by experience to be brutalizing instead of civilizing in its effects.

The writers of this paper, having personally visited the locality, and on two occasions during the last year witnessed the public whipping of a number of men in a neighboring State, have thought an account thereof might be acceptable to the Medical Jurisprudence Society and visitors present.

In view of the suggested renaissance in our commonwealth of this ancient form of punishment, the facts as noted, as well as those elicited from worthy citizens of the locality where it is in vogue,—those of the experienced and of thinkers upon the topic,—will be presented as fully as our limited time will permit.

We are all well acquainted with the history of that quaint old county-seat or penal centre of the forum of Delaware,—New Castle,—with its ancient flavor, the straggling old court-house, jail, and market-house grouped around a cobble-paved square, and its background of river, flat horizon, and hazy atmosphere.

In the rear of the brown-walled prison, enclosed by a rough-hewn stone wall, is to be seen the engine of justice, its heavy oaken stem upholding, at ten feet in the air, a large, square platform, like a huge brown toadstool. This, in turn, supports a T-shaped upright, capped, at five feet, by a horizontal cloven plank with two pairs of arm-holes, through which the wrists of felons are pinioned. These constitute the pillory. The centre-post below, or stem of the whole, bearing at its sides, at more than forehead-height from the ground, two stapled iron hasps, iron-pinned, is the "whipping-post."

At our first visit, the culprits, one by one, stepped into the open air from a rear door of the prison, already stripped nude as to the upper parts of the body, the lower clothing held by the hands as they in turn approached the post in company with the warden. He deftly placed the unresisting wrists within the iron loops on the sides of the pillar, exposing the naked back from above the waist to the sheriff, who stood at the left side poising in hand the formidable "cat-o'-nine-tails," while the warden, posted opposite, read loudly from a tally-sheet in hand the prisoner's name, offence, and sentence.

When this ceremony was concluded, the whipping began. The sheriff, lightly raising his arm, using the forearm only, struck, after a sweep of a small part of a circle and not too hard, blow upon blow on the smooth, naked back, while the warden's harsh voice counted and scored each stroke.

The heavy whip, with its square-edged, snake-like length of many roughened thongs (as may be readily credited on inspection), could be made a horrible means of agonizing torture; and, permit us to say, this is perhaps the real cause both of the seeming strength and real weakness of this penal mode. The infliction lacks precision, which is an essential of justice. Punishment by the lash can never be an exact quantity; it "is variability itself," to quote Bentham; and when compared with that executed by unvarying mechanism, as wrist-suspension, treadmill, shower-bath, or the "solitary" among other not unharsh mechanical forms, it is uncertain, indefinite, unmanageable, incomputable, unsatisfactory,—ranging in severity from a bloody, sickening, flaying butchery to a mere perfunctory dusting of the offending back, in direct proportion to the sentiment or venality of the acting official.

While the actual number of blows must be a matter of fact, as per sentence, the location, the amplitude, the force of each may vary, as we witnessed, at the option of the officer. Here enters the element of personality, or personal feeling, which should not be a factor in any legal punishment.

There was apparently in the cases seen, if we except a decided involuntary convulsion towards the whip, but little cringing on the part of the men, and close after-inspection of their backs showed neither elevation nor breaking of the skin. On questioning them, there seemed to be a decided absence of any great indication of punishment. Three of the seven addressed spoke in the lightest vein of the affair, two of them repeatedly asserting that they would cheerfully submit to a repetition in lieu of their short terms of imprisonment of some six or eight months.

Of the seven, two were white; and even in these the cuticle of the back was not visibly affected by the operation.

Need we add that the sheriff and warden, as is notably the case in our land, were men of intelligence and feeling, and offered us every facility for our investigations?

In three of the cases above noted, one hour had been spent previously wrist-held in the pillory's elevated stocks on each of our visits, the hats of the men having been kindly adjusted by the deputies as a protection against the May sun or the November snow. The sixty minutes spent in this cramped, unmoving position seemed trying only to the taller of the subjects, but while in the pillory, as while firmly clamped, facing the flogging-post, there was still to be noted a decided self-consciousness, and a spirit of bravado not unmixed with a certain mental exaltation which is often to be seen in the objects of a public administering of penalty. This coolness—not to say assurance—under fire was shown in the case of one of the two white men by the following incident. After the sheriff had done his work, the hands of the supposed sufferer being quickly released, he was about to move away, but stood still for some minutes at the calm request of a photographer (not from Philadelphia), who had not as yet made his slow picture.

The whole effect of this scene might have been ingenuously refreshing, were it not for the obvious legal and medical questions involved. The legal mind, we think, might have decided these unfortunates as "out of court," and fit subjects for the "reformatory" only.

To the medico-legal mind they were, as shown by their histories, offences, and development, "moral idiots." One of them (white) suffered for petit larceny; was a kleptomaniac: he was convicted of stealing goods which had been brought to his own house, the fruits of a "donation-party." Another, with the rude *alias* of "Sugar Awful" (colored), had stolen his way through life, from the "sugar of infancy" to the pair of shoes at nineteen years, and had been publicly whipped more than seven times. Of the men whom we saw whipped, but one received the "cat" for the first time. After ten lightly-applied lashes to one client, the official said in a stage-whisper to one of the writers of this paper, "I heard the evidence in that man's case, and I am not assured as to his guilt, so you see I let him off easily." "It is the first time he was whipped," he said, significantly, after another case, where he had struck but airily, allowing the thongs to spend their light force upon the waistband of the fortunate culprit's trousers. "Thank you, sheriff," said another to that officer, after the castigation.

These exhibitions are open to the public, in a certain sense, and when the gates of the court-yard were thrown open, on the hour, we noticed that the populace in this case consisted of perhaps a score of unkempt urchins,—these apparently from face and garb had come only from that boys' lack of other interest which is common to their kind,—a few colored idlers, the officials, newsmen, and one or two of the oldest if not the most respectable inhabitants.

The good people of the town, with one accord, seemed to shrink from the affair, and in conversing on the subject seemed to take but a melancholy and deprecatory interest,—one or two declaring to the writers that the "next session of the Legislature would or ought to relegate to deserved oblivion this form of penalty."

As an offset to censure, which is so easy, let us hasten to say that occupying the same cell with that "Sugar Awful" and his companion, noted above, were two colored juvenile burglars, whom we talked with, and who we were told would not be whipped, but sent to the "reformatory school" now being finished.

We saw with satisfaction that the effect of the fate of these juniors was noticeably good upon their two room-mates, veterans of the "cat."

Another informant (conversing upon the topic of public whipping) asserted that the judiciary, being perhaps among the most venerable and august, only permitted this archaic anachronism from the inertia of precedent. It would appear that conservatism, that excellence of law, prevents the dropping of this penal form from the code, but does not hinder it being but rarely and then only lightly applied, and that chiefly to almost the same luckless individuals, who are presumably "used to it"!

It is likewise to conservatism that the opponents of the rehabilitation of this mediæval punishment look for its non-success in this State. A well-known educated resident gave as his opinion that whipping was a farce, the letter of the law and not its spirit,—the same culprits regularly returning to be whipped two, three, and four times. "However," he

said, "the increasing influx of immigrant artisans and residents from other States is rapidly leavening the community into broader views."

The facts reached by talks with the inmates of the jail showed that this punishment was never unaccompanied by, but was always additional to, imprisonment; that flagellation was entirely without any admonitory or preventive effect; was the award only of the lesser misdemeanors,—those against property and not against persons,—petty theft and larceny; was not a part of the sentence in the greater offences; was not unfrequently remitted by the pardoning power; was not applied to the more ambitious class of malefactors. The unanimous expression of the men within the bars was that the "odium of the lash" clung to one inevitably and irrevocably; while the stigma of imprisonment was not recalled, and did not leave the same evil reputation.

One man who has been for some time, and is now, incarcerated was flogged some years since to the extreme of cruelty, and, in the words of the officials and his fellow-prisoners, as well as his own, "this was the result of personal and family spite on the part of the powers that were and acted."

The penalty is, the writers think, retributive or retaliative, and Bentham says retaliation is "too expensive:" it "is incompatible with that apportionment which the law ought to make of the punishment to meet the several circumstances of aggravation or extenuation found in the offence."

The same venerable "utilitarian" authority quotes the "Arabs as being a vindictive people, to whom the retaliative laws of the Koran were pleasing," and quotes the "Chinese as endeavoring to govern the uncertainty and variability of flogging by iron rules as to the length and thickness of the bamboo to be used." But, to use his words, "the element of uncertainty is the degree of force of the stroke,—there as here." Again he says, "Its infamy is its weakness." In his book, "The Rationale of Punishment," as quoted above and as follows, he says, "Acute corporal punishments are exceedingly uncertain, unequitable; are extremely variable in intensity, but not in duration; the evil of the punishment must not exceed the evil of the offence: it is unprofitable if the official produces more than he has prevented."

Thus we have stated the economics of punishment according to Bentham.

Sir Edmund Du Cane, Inspector and Surveyor-General of Prisons, in his work published in London, 1885, states that "The pillory was there abolished in 1837; women were whipped, not always in private, almost to the end of the eighteenth century; and, while the enactment providing for flogging has not been repealed, public opinion has not permitted it for many years; that the Scotch law permitting schoolmasters to use the rod is honored not in the observance."

E. W. Cox, Serjeant-at-Law and Recorder of Portsmouth, England, in his work, London, 1877, says that "The very visible harshness of ignominious punishment, by inevitably rupturing the family relation of wife and children, will prevent in the greater number of cases the beaten wife from testifying against her brutal husband." This, please notice, in thickly-peopled England, where wife-beating is perhaps indigenous.

The Constitution of Pennsylvania of 1776, in the Bill of Rights, Section 39, Article II., says, "To deter more effectually from the commission of crimes by continued visible punishments of long duration, and to make sanguinary punishments less necessary, houses ought to be provided for punishment by hard labor," etc.

The Constitutions of Pennsylvania, both of 1790 and 1838, agree verbatim in the provision that prevents "cruel or unusual punishment." That of 1873, as amended, prohibits "cruel punishments."

One of the writers of this paper believes with Bentham, already quoted, that "could the variability of the penalty be removed by constructing a machine of rotating cylinders armed with a definite number of rattan-canes revolving at a known speed,—thus removing the personal factor which might be venial or sentimental,—then only would the punishment of whipping be admissible."

Facts, the other writer believes, bear him out in the statements that flagellation is not admonitory, is demoralizing and destructive of those better feelings, incentives to right-doing, inherent from education more or less in all men, and called conscience. It is not reformatory,—the victim's self-respect, in whatever de-

gree possessed, being rudely shocked; its very brevity admitting no thought, no repentance. It is in a degree ignobly, violently final, and no act of a pardoning power can restore the former condition. It is retaliatory, and would fulfil, in the circumstances under which its revival is thought of, the Hebraic law of "an eye for an eye," etc. Its sharp brevity outweighs its seriousness as a penal mode. It is reflected ignominiously upon wife and children, though desired to be aimed at her and their protection. It is brutalizing to the recipient, to the flogging officer, to the witnesses, to the community; being essentially a gruesome relic of that other relic of feudal barbarism, chattel-slavery!

To descend to the *argumentum ad hominem:* not the flogging, retributive teacher was the guide of our youth, but that one —admonitory, reformatory—who taught, guiding by unwavering but kindly firmness, iron-handed in a velvet glove, our wayward footsteps towards whatever of good may have been reached in life. This spirit, we think, is the spirit of the penal law of to-day.

In answer to letter-inquiries addressed by the writers of this paper to a number of experienced observers of this mode of punishment, the following responses were received. The police-captains of the several districts of Baltimore, six in number, are about evenly divided as to the effect of the law, now and for the last two years in force in that commonwealth, punishing wife-beaters at the whipping-post.

One captain writes, "The first case in my district was a colored man, charged with brutally assaulting his wife, tried, and sentenced by court to twenty-five lashes. Almost immediately after the sentence had been executed, the offence was repeated. In my judgment, the flogging of a white man is degrading, does not improve his moral nature, and is not a preventive of crime."

Another captain replies, "In answer to your inquiries as to the law inflicting whipping as a punishment for wife-beating, I beg leave to give the following opinion. I am unable to say that it is altogether a preventive, as a large majority of wife-beaters are men of drunken habits, who when sober regret having committed the offence, and when drunk know not what they do."

Another captain says, "There have been only two convictions in the criminal court under the law, and I find in the district of which I am captain that there are now very few arrests for assaults on wives, where before it was of almost daily occurrence, and I think to some extent the wives do not make complaints against their husbands as formerly."

Another captain responds, "It has had the very best effect, and we do not have half the number of wife-beating cases in the Eastern District that we had before the passage of the above law. The brutes dread the lash. I think, though, there are many cases where the wife silently submits to the cruel treatment of her husband rather than have him arrested and disgraced at the whipping-post."

Again, one captain writes, "Since the whipping-post law was inaugurated and men have suffered the penalty for brutally beating their wives, the offence has been less frequent. Whether this state of affairs is due to the severe punishment cannot be definitely ascertained; but the probabilities are that the law acts as a preventive. Men of the class of wife-beaters are deterred by the fear of physical suffering under the lash and of the disgrace consequent upon their undergoing the penalty. One partial explanation, however, of the comparative infrequency of the crime at present is the unwillingness of a woman to prefer a charge and afterwards testify against her husband, however brutally he may have beaten her. This fact was obvious before the law was passed, and naturally would be the case in a greater degree now. As to the reformatory and moral influences of the whipping-post, for both may be considered together, it is my humble opinion that they are null and void. True reformation is not compassed by means which, as experience in general demonstrates, tend to harden and brutalize a man. Reformation is produced by influences which appeal to the better nature of a human being; but, the castigation once administered, the offender goes out again into society reformed, it may be, in the one particular of wife-beating, but with such bitterness against the law and society which countenances that law that he may be led to commit wrongs against society greater than his original offence."

The same inquiries to the warden of Sing Sing Penitentiary brought this reply: "We have dispensed with flogging, tread-

mill, shower-bath, and all other punishments in this prison except the dark cell and suspension by the wrists. In my opinion the world is advancing, and going back to flogging as a means of punishment is a step backward towards barbarism, and consequently public whipping would lower the standard of public morals."

The warden of Joliet Penitentiary, Illinois, answers thus: "I have never seen a case of public whipping, and consequently know nothing of its effects from observation. My impressions are against it as a reformatory or preventive measure."

A letter of inquiry addressed to Hon. Frederick Douglas, ex-marshal of the District of Columbia, drew the following from that monumental man of his race:

"WASHINGTON, D.C., April 22, 1886.

"DEAR SIR,—If for any offence in the world a human being should be stripped to the waist and lashed till his warm red blood shall stain the earth beneath, it is the offence of subjecting his wife and the mother of his children to that torture; but I am not sure of the wisdom of this sort of retaliation. In resorting to flogging, something more should be thought of than the just punishment of the offender. We must consider the effect upon the man thus punished and the man who is required to administer the punishment; and if we succeed in whipping the brute out of the one and at the same time only whip the brute into the other, little has been gained to humanity and decency by the operation. I know of few things better calculated to blunt and destroy all humane sensibilities than tearing the living flesh of a man with a blood-clotted cow-skin. The man who does it is unfitted for all moral and humane influences, and diffuses brutality in every breath. Sad, indeed, it is for the world, if only by flogging can men be made to refrain from beating their wives. Wife-beating is generally the result of drunkenness. Men do not beat their wives when they are sober. The wise thing is not flogging the wife-beater, but to do away with that which makes him a wife-beater, and that is strong drink. I am for putting it out of the power of a man to get that which tends to make him such a brute. Prohibit the sale of ardent spirits, shut up the saloons, break up the drinking habit, and you will soon be rid of wife-beating.

"Coming from a condition of slavery as I have, where everything was done by the whip, I have perhaps a greater horror of flogging than I might otherwise have. Be this as it may, I would try many other expedients before I would resort to the whipping-post as a remedy for wife-beating.

"I write in haste, but I have said enough to indicate my views on the point upon which you have done me the honor to ask my opinion. Truly yours,

"FREDERICK DOUGLAS.

"To G. MILTON BRADFIELD, M.A., M.D., Recorder of the Medical Jurisprudence Society of Philadelphia, Pennsylvania."

REPORT ON TOXICOLOGY AND STATE MEDICINE.

BY GEORGE H. ROHÉ, M.D.

(Continued from vol. xvi. page 925.)

II.—STATE MEDICINE.

ADMINISTRATION OF SANITARY LAWS.

DR. O. W. WIGHT, the efficient health-officer of Detroit, read a paper before the Michigan State Medical Society, in which he pointed out the necessity of a new plan of public sanitation. He proposes that the county shall be the unit of sanitary administration. A tax of ten cents per capita should be levied by the State for sanitary purposes. In a county of thirty thousand inhabitants this tax would produce (if collected) three thousand dollars per year. One-half of this should go to pay the health-officer, who should be a physician; the other fifteen hundred dollars should pay the salaries of a clerk and an inspecting-officer. There should be a county board of health, composed of two physicians and one lawyer, to serve without compensation. They should be appointed by the board of county commissioners; the board of health should appoint the health-officer, and the latter should appoint his clerk and inspector. "The health-officer thus appointed, before qualifying and entering upon his duties, should be required to undergo an examination by the State board of health, for the purpose of having his fitness for the place fully determined. In addition to his medical knowledge, he should also know the elements of sanitary engineering, of chemistry, and of the law of nuisance; he should be perfectly familiar with the laws which he is to administer; his executive capacity and his character for industry, impartial justice, discretion, and moral courage should be taken into consideration. His tenure of office should be during good behavior, and he should be clothed by law with the necessary powers of independent action."

[When the millennium arrives, some such

scheme as that proposed by Dr. Wight may work. His own experience with boards of health and council committees has doubtless shown him that his plan is premature. The model health-officer for years to come will be of the prevailing type of ignorant, time-serving politician. Whether he has M.D. as a pendant to his name does not much matter. In fact, the medical politician generally has even less backbone than the other sort when the "boss" demands places in the department for his favorites.—R.]

THE UTILIZATION OF SEWAGE.

Want of success in disposing of solid excreta, whether collected by means of the dry-earth, Rochdale, or Liernur systems, has led American sanitarians to turn hopefully to the intermittent infiltration system, as practised in many places in Great Britain, Germany, and France. In this country the system—in combination with the separate system of sewerage—has been adopted at Pullman, Illinois, and Atlantic City, New Jersey,—in both places, it is stated, with great satisfaction. At the insane asylum at Norristown, Pennsylvania, Colonel Waring (this journal, April 30, 1886) has recently completed a plan of drainage, with ultimate disposal of the sewage by irrigation, which seems to be complete in every particular and to answer all the demands of sanitary science. Colonel Waring, who has studied the subject more thoroughly perhaps than any other engineer or sanitarian in this country, has arrived at the conclusion that the system of sewage-disposal by intermittent surface-irrigation "answers every requirement of simplicity, safety, and decency."

CREMATION OF GARBAGE.

The disposal of refuse by burning has been advocated by many sanitarians. At the last meeting of the American Medical Association a good paper (not yet published) was read upon the subject by Dr. G. S. Franklin, of Ohio, and at the sanitary convention of the Pennsylvania State Board of Health a description was given of an apparatus designed to dispose of human excreta in this manner.* J. Zellweger† also publishes designs of a garbage-furnace, and points out the requisites for such an apparatus. According to the latter writer, the cremation of garbage consists of several distinct processes, classified as follows: (1) drying of the fresh charge, (2) destructive distillation of the dry matter, (3) burning of the remaining charcoal and coke, and (4) decomposition and oxidation of the organic vapors and gases produced in drying and charring the garbage.

"These several processes must be carried on separately, and in different parts of the furnace, so that the consumption of heat does not interfere with its production. It is essential, for the successful cremation of garbage, that the full calorific power of the fuel be developed and all the available heat be transferred to the fire-gases before these are allowed to mingle with the aqueous vapors and organic gases rising from the fresh charges in the furnace. The heat produced by the combustion of charcoal, coke, and the gases expelled by destructive distillation is then brought to act upon the gases mingled with and protected by steam to decompose them, and to cause their oxidation in the accompanying air."

The furnace designed by Mr. Zellweger seems well adapted for securing the results above stated at a reasonable cost.

The Health Committee of the Wheeling (West Virginia) Common Council has recommended the adoption of the system in that city. It is said that a furnace of sufficient capacity for the purpose could be constructed for two thousand and fifty dollars, but no estimates are given of the cost of running the same. Wheeling had a population in 1880 of 30,737.

PROPRIETARY AND PATENT MEDICINES AND THE PUBLIC HEALTH.

Dr. Frank Woodbury, in a paper read before the Pennsylvania State Sanitary Conference,‡ called forcible attention to the alarming frequency with which narcotics, stimulants, and other classes of medicines were consumed by the public without directions of a physician. In view of the absence of all effectual restrictions upon the sale of medicines in this country, he advocated the following conclusions:

1. The examination of all proprietary medicines by a government or State commission of experts, which shall have power to permit the sale of such as are harmless or especially likely to prove serviceable,

* Annals of Hygiene, August 1, 1886.
† Sanitary News, February 27, 1886.

‡ Annals of Hygiene, August, 1886.

and to prohibit the sale of all which are liable to do injury, and particularly those which are found to be worthless and frauds upon the public. Such a commission was appointed by the Japanese government several years ago, and has been found to be of great service in that country.

2. The instruction of the public to properly estimate drugs, and to regard every unknown medical agent as dangerous and endowed with capacity for harm. Let them endeavor to escape the caustic criticism of a Molière upon those who "pour medicine about which they know little, into bodies about which they know less, in order to cure disease about which they know nothing at all."

TYPHOID FEVER AND POLLUTION OF DRINKING-WATER.

Dr. Charles Smart, Surgeon U.S.A., read an excellent paper before the Pennsylvania Sanitary Conference upon "Wholesome Water for Cities and Towns" (this journal, June 26, 1886), in which statistics are given to show the influence of an impure water-supply upon the spread of typhoid fever. Thus, for the past ten years, the average annual mortality from typhoid fever for every 100,000 of population was 66.1 in Philadelphia, 52.5 in Baltimore, and 24.6 in New Orleans. The water-supply of Philadelphia is contaminated with sewage; that of Baltimore, generally pure, is partly drawn from pumps, which necessarily furnish exceedingly impure water; while that in New Orleans, being almost exclusively rain-water, collected in cisterns above ground, is little subject to sewage-pollution. The result is shown in the typhoid mortality, which is less than half of that of the sewered city of Philadelphia.

BRASS-FOUNDER'S AGUE.

A graphic account of the group of symptoms known under the above name is given by Hirt, in his work on the Hygiene of Occupations. This author had two attacks himself, and is therefore competent to describe the symptoms, which he does as follows. "A few hours after attending the process of brass-casting, one notices a peculiar, uncomfortable sensation over the whole body. More or less severe pains in the back and general lassitude cause a discontinuance of the ordinary occupation. While the pains appear now here, now there, and are extremely annoying, no changes in the pulse or respiration are noticeable. In a short time, however, usually after the patient has taken to the bed, chilliness comes on, which soon increases to a decided rigor, lasting fifteen minutes or longer. In the course of an hour or less the pulse now reaches a rapidity of 100–120 beats per minute. A tormenting cough, combined with a feeling of soreness in the chest, comes on. In consequence of the repeated acts of coughing, the increasing frontal headache produces extreme discomfort. Soon, however, usually after a few hours, the height of the attack is reached, free perspiration indicates the stage of defervescence, and during the gradual diminution of the symptoms the patient falls into a deep sleep, lasting several hours. On awaking, a slight headache and lassitude only remain as reminders of the attack."

Although it is said that about three-fourths of all the workmen in brass-foundries suffer at some time from this affection, reports of cases are rare. This will give point to one related by Dr. Suckling.* The man worked directly over the casting-shop, and whenever any casting was done he had an attack, the symptoms corresponding pretty nearly with those above quoted from Hirt. Dr. Suckling found benefit from the administration of iodide of potassium.

It is uncertain whether the symptoms are due to the fumes of the copper or of the zinc used in making the alloy. Perhaps both are partly responsible.

PROPHYLAXIS AGAINST DISEASE IN FACTORY-LABORERS.

At the meeting of the American Climatological Association held in Philadelphia, May 10 and 11, 1886, Dr. J. H. Musser made some practical suggestions looking to the prevention of that state of the system which often leads to phthisis. He believes, no doubt justly, that ill health in mill-operatives is often due to lack of sufficient food. He stated that a large cotton-manufacturing company, the Willimantic, had introduced an excellent plan to preserve the health of their operatives, and urged that all the members of the Association should endeavor to secure its general adoption by factory-owners. The plan consists in supplying the operatives twice

* British Medical Journal, March 27, 1886.

daily with good, easily-digested food ; the boys receive milk, and the women bouillon, by which is probably meant a soup or broth, and not beef-tea, for the latter has little food-value.

SANITARY INSPECTION OF SCHOOLS.

In Hungary the following regulations governing the sanitary administration of schools have recently been established :

Every middle-class school is to have a medical officer, who will receive an annual salary of two hundred florins in schools where a complete course of instruction is given, and one hundred florins in other schools. He must examine all the pupils at the commencement of each scholastic year, and keep a constant watch over their health, and must give special attention to the prevention or eradication of infectious diseases. He will also give advice during gymnastic exercises. He will also keep watch over the instruction in general, and if he observe any deleterious influence in operation, with regard either to the whole school or to individual pupils, he will bring the same to the notice of the director of the school. In the upper schools he will give instructions in hygiene for two hours each week to those pupils of the higher classes who may desire to receive it, the subject being treated in an easy and popular manner.

In Paris, also, regulations governing the sanitary administration of schools have been adopted. In the girls' schools a young woman with a medical education has been appointed a sanitary inspector. Her duties are to see that the girls are not overworked, and that they perform their tasks under the best sanitary conditions possible. This is a long step in advance. Its adoption by school authorities in this country will mark the beginning of a new era in public hygiene.

A HYGIENIC SCHOOL-DESK.

Dr. Priestley Smith* states that a hygienic school-desk must have the following requirements :

"1. The seat must be of such height as will allow the scholar's feet to rest flat upon the floor or foot-board, and broad enough to support the greater part of the thigh.

"2. The seat must have a back placed at such height as to fit the hollow of the back below the shoulder-blades and support the body in a vertical position.

"3. The near edge of the desk must be just so high above the seat that when the scholar sits square and upright, with elbows to the sides, the hand and forearm may rest upon the desk without pushing up the shoulder.

"4. As used in writing, the desk must have a slope of 10°–15° (about 1 in 5). As used in reading, it must support the book at an angle of about 45°, and at a distance of at least 12 inches from the eyes : 16 inches is better (30–40 cm.).

"5. As used in writing, the edge of the desk must overhang the edge of the seat by an inch or two, in order that the scholar shall not need to stoop forward, and that the support to the back may be maintained.

"6. Either the desk or the seat, or some part thereof, must be movable at pleasure, so that although the desk usually overhangs the seat, the scholar may be able at any time to stand upright in his place.

"7. The desks and seats must be of various sizes, in order that the foregoing conditions may hold good for scholars of various ages."

[The reporter, in his "Text-Book on Hygiene" (Baltimore, 1885, p. 157), had already distinctly formulated these requirements. But sanitary preaching will have little effect upon matters of school hygiene until sanitarians become members of school-boards, and sanitary inspectors in fact, and not in name only, are a recognized part of the school administration.]

TRANSLATIONS.

INDIRECT INNERVATION OF THE SKIN.—At a recent meeting of the Academy of Sciences, M. Vaulair, in a note on the indirect innervation of the skin, stated that in numerous instances it had been observed that sensibility remained after some of the principal nerves had been cut. In some instances sensibility of the peripheral nerve-end remained intact, though totally severed from its central extremity. MM. Arloing and Tripier have demonstrated that recurrence, added to the further fact of peripheral diffusion of the nerve-fibres, explains the apparent paradox of the existence of sensibility in the peripheral nerve-end after section, and, therefore,

cutaneous sensibility. These hypotheses, based on the excellent scientific researches of MM. Arloing and Tripier, have been accepted by all physiologists. But these investigators, believing in an intimate relation between these two phenomena, have neglected to define the part played by recurrence, also that of the collateral diffusion of the fibres, and have likewise passed unnoticed the return of sensibility after its preliminary suppression, occurring independently of nerve-regeneration.

These special points M. Vaulair has by experimental research striven to elucidate, and concludes from his researches that recurrence and collateral diffusion are two thoroughly independent phenomena. The latter is by far the most important, and alone assures cutaneous sensibility. After severing the nerves, exchange of nerve-force among the peripheral nerves occurs among branches of the same nerve; also among nerves belonging to the same plexus. The collateral fibres travel into the deep tissues of the limbs, issue from the surface of the aponeuroses, and separately penetrate into the skin. Suspension of sensibility does not result from paralysis of the peripheral end, but from an inhibitory action proceeding from the spot presenting lesion and gaining the centre of the fibres attacked; thence it spreads to the neighboring nerve-centres. This influence is gradually exhausted, and thus sensibility gradually returns.

Chemical Characters of Urethan.—At a recent meeting of the Academy of Sciences, M. Berthelot presented a note by M. G. Jacquemin on urethan and its analysis. If mercuric chloride be first added to a solution of urethan, and then potash, a white precipitate is deposited. If this substance be heated with urethan in excess, it dissolves and is precipitated while cooling. With an excess of potash it becomes yellow, and is mercuric oxide, perfectly insoluble in water. This mercuric oxide, precipitated, dissolves under the influence of slight heat when passed into urethan; on cooling, it leaves a white precipitate.

M. Jacquemin states that salts of mercury at one and a half per cent. can be again precipitated. Weaker solutions—.00005 gramme of urethan to every cubic centimetre of solution—are treated with potash and mercuric chloride added drop by drop. A yellow precipitate forms, then dissolves as long as urethan is present, but it is afterwards again precipitated. This reagent is useful in a volumetric analysis. Mercuric nitrate and mercuric acetate in the presence of urethan behave towards potash like chloride. Both these mercury salts precipitate urea, but precipitate urethan only in the presence of potash.

M. Jacquemin utilizes his investigations to detect urethan in urine. Normal urine, even when considerably diluted with water, treated with this reagent gives a white precipitate, which blackens with ebullition. Therefore urethan present in urine must be eliminated. The investigator uses ether. The deposit of the evaporation of the ether is dissolved in a little water and treated according to the method described above.

The Physiological Function of Pulmonary Tissue in regard to Carbonic-Acid Exhalation.—The tension of the carbonic acid in the air contained in the lungs is considerable. Wolftberg and Nussbaum have shown in their works that the tension of carbonic acid in arterial blood is almost the same as that of this gas liberated in the pulmonary alveolæ. Pulmonary exhalation of carbonic acid is submitted to unfavorable physical condition. M. Garnier, at a recent meeting of the Academy of Sciences, described his researches made in order to ascertain if a chemical action does not facilitate the liberation of carbonic acid when in contact with the air contained in the pulmonary alveolæ. Chemical analysis did not succeed in extracting a definite acid, but pulmonary tissue taken from different animals (oxen, sheep), cut up in cold water, furnishes a fluid which, when mixed with blood which is alkaline, remains slightly though distinctly acid, and this acidity is not due to carbonic acid. Ultramarine injected into the lungs of a rabbit becomes discolored after it has been allowed to remain there twenty-six days. This discoloration could not take place in the absence of a strong acid: taurine and carbonic acid are both inert.

M. Garnier believes that there exists in the pulmonary tissue a substance which acts as an acid. This acid has evidently an action on the carbonic combinations of venous blood which leads to the liberation of carbonic acid.

PHILADELPHIA
MEDICAL TIMES.

PHILADELPHIA, OCTOBER 2, 1886.

EDITORIAL.

THE NEW VOLUME.

THE present is the first number of the Seventeenth Volume of the *Philadelphia Medical Times*. During the coming year, arrangements have been made for the publication of original articles by well-known writers, the clinical department will have special consideration, while reports of medical progress and notes from medical centres of the world will continue to occupy a prominent position in these pages. We invite our readers to add their individual contributions of rare cases in practice, of interesting observations on the post-mortem table, and of the action of old or new remedies; and, to further this end, medical questions and replies and letters from the profession will find a welcome place in the *Times*. Let each subscriber put himself down for at least one contribution to its pages during the year. For all original articles the publishers will furnish reprints in a neat octavo form, with cover, or will pay their equivalent in money if preferred. Correspondence containing early medical news will be especially acceptable.

THE THERAPEUTIC ACTION OF SPARTEINE SULPHATE.

ACCORDING to MM. Laborde and Légris,* sparteine, the active principle of the broom-plant (*Cytisus Scoparius* Link), has valuable properties as a cardiac tonic, since it renders the heart-beats stronger and more protracted: its action is considered essentially *dynamogenic*. That this influence is central in origin, the absence of alteration in vascular pressure or in peripheral or vaso-motor effects constitutes one of the important proofs; which is further corroborated by other phenomena, among them those belonging to convulsions and asphyxia, showing its depressing influence upon the respiratory centres. In frogs, for some time after actual death, even when the animal begins to dry up, the heart still beats rhythmically, showing that sparteine gives an impetus to the contraction and increases the length of the beats. MM. Laborde and Légris observed similar phenomena in new-born puppies. No other influence proceeding from the nervous system can be supposed to act in this case than that of the intracardial ganglia. Any other hypothesis would necessitate the concomitant and the direct contraction of the muscular fibres of the heart. The myographic researches made by these investigators have not at present furnished results that warrant decided conclusions.

The therapeutic properties of sparteine, as formulated by M. Sée in a recent paper to the Académie des Sciences, agree with the physiological effects: it revives the heart-beats and the pulse. In this respect it equals digitalis in action and resembles convallamarin. As a tonic it is more active than these, as its effects have been found to be more prompt and more lasting. It also regulates the rhythm in cardiac disturbance, and in this effect it is said to be superior to any other of the so-called heart-tonics. In serious atonic conditions the heart-beats are quickened: in this respect sparteine resembles belladonna. The favorable modification resulting from the action of sparteine in clinical observations usually occurs in one hour, or in some cases a few hours, after its administration, and continues two or three days. During this time the general strength is increased and respiration is rendered easier. The urinary function appears not to have

* In an article entitled "La Méthode expérimentale appliquée à l'Etude des Substances médicamenteuses," published in the *Archives de Physiologie Normale et Pathologique* of May, 1886.

been influenced by such small doses as those hitherto used.

The more recent researches made by MM. Laborde and Légris lead them to endorse M. Sée's statements, and they further state that the action of sparteine is quicker and more rapid than M. Sée observed it to be. The daily dose of sulphate of sparteine varies from five to twenty-five centigrammes.

Sparteine may with advantage be administered under the following conditions. When the action of the heart is weak, either from alteration of tissue or because it cannot overcome obstacles offered to the circulatory system. When the pulse is irregular, intermittent, arhythmic, it is impossible to arrive at perfect regularity, except in those cases where the absence of rhythm and intermittence are the result of advanced cardiac degeneration or an atheromatous condition of the coronary arteries. The prompt action of sparteine renders it invaluable in heart-disturbance requiring immediate treatment. In instances of asystole it has been considered preferable to any other drug. In all cases of weak heart, with asthenia, sulphate of sparteine may be used whether there is lesion or not; since MM. Laborde and Légris declare that they do not know any conditions that should be regarded as contra-indications to the use of sparteine. It is not a cumulative substance in small doses, and apparently does not exercise a deleterious effect either on the digestive organs or on the cerebro-spinal system. It can be used for some time without an interruption being necessary. When digitalis is given, sparteine sulphate may be used as a substitute with advantage in the necessary intervals of administering the remedy. In cardiac affections accompanied by dropsy an infusion of broom-flowers added to sparteine sulphate has a beneficial effect, by increasing its effects as a diuretic. In cardiac dyspnœa the iodide of potassium may often be used with advantage in addition to sparteine, and pyridine inhalations administered.

MULTIPLE NEURITIS.

UNTIL within a very few years the tendency to refer a large number of obscure trophic, sensory, and motor troubles to lesions of the cord, and especially to lesions of the anterior cornua, was very general. Hence these affections came to be regarded as symptomatic of various forms of poliomyelitis anterior. Just now the pendulum is swinging the other way, and there is a growing—perhaps already an exaggerated—disposition to ascribe those manifestations not to central but to peripheral causes. Disorders, such as we refer to now, suggest, in place of some spinal affection, more or less generalized alterations in the nerves themselves. Hence the frequent recurrence of such terms as multiple neuritis, polyneuritis, and peripheral neuritis in the observations of the neuropathologists.

Many of the cases are characterized by symptoms by no means restricted to a limited region of the peripheral nervous distribution, but, as Lucas-Championnière insists upon in a recent article (*Journal de Médecine*, July, 1886), they were characterized by phenomena sufficiently extensive to realize the type of paraplegias, partial paralysis of all four limbs, or even a general paralysis to such a degree that the differential diagnosis from paralyses of central origin is extremely difficult.

Among the chronic forms of multiple neuritis, one of the more interesting is pseudo-tabes. But the acute forms are of not inferior interest, especially as their study has been rewarded by fresh knowledge in the direction of causation. The causes of these forms of neuritis at present arrange themselves into three principal groups: 1, intense or prolonged cold, especially under circumstances of great fatigue; 2, toxic, among which alcohol holds chief place, although arsenic and

lead are important; and, 3, infection. The third etiological group includes such acute and chronic infective diseases as relapsing fever, variola, diphtheria, rheumatism (which seems to have especially close relations with polyneuritis), syphilis, and tuberculosis. To these we would add enteric fever.

The symptoms are, however, but little modified by special causes.

The cases are acute, subacute, and chronic. The palsy is usually ascending, in many cases first attacking the lower extremities symmetrically, then the upper extremities, and finally the trunk. It may, on the other hand, remain limited, or chiefly affect one side. Muscular atrophy more or less marked is an almost constant symptom. The reaction of degeneration is present in varying degrees. Among the manifestations of trophic changes are œdema of the extremities, dryness and roughness of the skin, pigmentation and erythematous patches, eczema, abundant sweating. Anæsthesia is less common than hyperæsthesia. Paræsthesia is constant, often manifesting itself as pain.

The march of the affection is irregular; its terminations are equally inconstant. Sudden death, equally sudden restoration to health, gradual improvement, and a chronic, little-varying condition, with fair general health, have been noted.

Alcoholic paralysis, first described by Jackson, of Boston, in 1822, later by Huss, Lancereaux, Leudet, and Wilks, and very recently fully studied by Broadbent, Déjérine, Hun, Dreschfeld, and others, is the best-known form of peripheral neuritis* of toxic origin.

Like other alcoholic affections, alcoholic paralysis does not differ in its symptoms from similar conditions due to other causes, and hence cannot be looked upon as a specific disease. Full recovery usually follows the discontinuance of alcohol.

* For a fuller summary of the present knowledge of alcoholic paralysis, consult Dr. J. C. Wilson's article "On Alcoholism" in vol. v. of Pepper's "System of Medicine."

THE DISTRICT NURSE SOCIETY. — In the last issue of the *Times* a short notice of a very useful charity was given, to which we again direct attention. The organization has been formed for the purpose of supplying experienced attendants for the poor. The nurses sent out by the Society work in both the third and the fourth district, and are therefore available for cases between the Schuylkill and Delaware Rivers and South and Vine Streets. The office is at 1203 Race Street, where all needed information will be furnished upon application.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

MEDICAL and Surgical Congresses.— Europe has been quite prolific of this sort of meeting this summer. Notices of that at Brighton and those in Germany you already have from your other correspondents, so that we can remain local and give only the most important points of the French Congresses. "L'Association française pour l'Avancement des Sciences" held its fifteenth session this year at Nancy. Its newer therapeutical ideas will occupy most of our letter with what was, perhaps, the most interesting part of the proceedings. M. Paul Landowski, of Paris, spoke of local treatment in membranous dysmenorrhœa. He had found, as the rule, that this affection attacked women who were under the influence of a diathetic state of general debility which may or may not be cachectic; but that this condition was not at all absolute, because, oftener than is usually thought, young and strong women, and girls full of health, are found to be suffering from this complaint without any apparent cause. In these cases the disease will remain localized for a long time before extending to the whole organism and causing a debilitated and anæmic state. Where this form of exfoliative dysmenorrhœa is the result of a general cachectic state, the treatment must, of course, be directed to the constitution; but in all cases it is advantageous to adopt a local treatment. Indeed, it becomes the most important part of the therapeutical application in those cases where the affection is primitive and localized. The author therefore proposes the local application of the electrocautery to the endometric surface, and lays down the following rules to make the treatment successful. First, It is of great impor-

tance that the operation should not be performed until the uterine orifices are fully dilated. If they are naturally large and easily dilatable, one application of prepared sponge will be sufficient; but if they are rigid, two must be made,—one the evening before the operation, and the second the next morning. The moment the sponge is taken out, while the cavity is wide open, is the time to introduce the electro-cautery, which should be rapidly heated to a dull red, and passed lightly all over the endometric surface. With careful touch, and these precautions, the author claimed that there is not the slightest danger to be apprehended. After the operation the patient must remain in bed for a week. Care must be taken to make the application five or six days *after* the cessation of the monthly period.

M. Netter, of Nancy, proposes to treat whooping-cough with the "Oxymel scillitique," made according to the French "Codex," and given pure. Soubeiran's method of making the oxymel of squill is the one followed here: dissolve six parts of the alcoholic extract of squill in fifty parts of vinegar, filter, and combine *secundum artem* with two hundred parts of honey. The vinegar seems to destroy the irritant action as well as the emetic property of the squill, and increases the expectorant effect. It is recommended to be administered pure every ten minutes for one hour daily. Dr. Netter first of all remarked that when it was given in bronchitis (as for the last twelve years had been his habit during the period of sibilant râles) it produced an abundant bronchial secretion, which led him to try this form of medication in whooping-cough. Professors Hecht, Rémy, and Schmitt, of Nancy, besides the author, have all tried the method proposed, with great success. In two or three days, or even less, the cough becomes easy (what the French call "grasse"), and the mucus comes easily into the mouth. From this time the cure depends on the age of the child, according as it is able to spit out the mucus or is compelled to swallow it. In strong boys the most violent whooping-cough has been seen to improve in two days after the administration of the medicine. In weaker children, or those under three years of age, it does not relieve quite so well, but, with the use of an emetic, the cure is accomplished almost as soon. In babies still at the breast, from twenty to forty drops of the medicine are enough, and it usually is found to answer very well. Non-success will be found to be owing to the bad quality of the preparation, or to its irregular administration. All old or stale preparations should be rejected. The following system of giving the remedy was found to be the best. At half-past three P.M. give the child his lunch, then between five and six o'clock give him a teaspoonful of the oxymel *every ten minutes during this hour.* Give in all four to five at three years of age, six to seven over that age, and seven to eight teaspoonfuls in adults. Then let them have their dinner at seven P.M. Continue each day in this way, during *this one hour only*, until the coughing-fits are over. M. Rémy, of Nancy, confirmed what his colleague had stated in regard to this treatment, and said he had seen several cases of cures by this method, and that the amelioration, in his experience, had been rapidly brought about, —mostly within three days.

Dr. Henri Huchard, physician to the Bichât Hospital, Paris, presented his observations of cures of angina pectoris by means of the iodides, and added four new cases of great improvement, even cure, in arterial cardiopathic cases taken at their commencement. Arterial sclerosis he looks upon as a general disease which acts on the heart, kidney, and brain, and the only proper medication is that which has its action on the arteries,—*i.e.*, the iodides. One of the considerations which the doctor dwelt upon at length was that it was an essential condition of success to prolong the action of the remedy during a period of from one to three years continuously, at a daily dose of one to three grammes. Much importance was also laid by the speaker and those agreeing with him (such as Professor Bouchard, of Paris, Dr. Liégeois, and others) on the fact that the iodide of potassium is a very toxic salt, while the iodide of sodium is forty-two times less so: therefore this last salt is strongly recommended to be used, in these cases at least.

M. de Pezzer spoke of the use of naphthaline in the treatment of genito-urinary diseases. It had been used by Rossbach, in 1884, in doses of one and a half grammes to prevent intestinal putrefaction, and he had found in urinary troubles that the results are just as satisfactory. When the urine was fetid and there was difficulty in micturition, the dose used was one gramme divided into twenty-five centigramme pills; but the eructations were found to be very disagreeable with this mode of preparation, and capsules of gluten were then substituted with great benefit. Oil of turpentine had been tried, but it failed in several cases which subsequently improved under naphthaline. In all the cases where the urine was cloudy, purulent, alkaline, or full of microbes, it became limpid, neutral, or acid, after the remedy was given, while the quantity of pus, if any had been present, decidedly diminished or entirely disappeared. In cystitis or pyelo-nephritis, and in the many cases of old urinary diseases that so often occupy the beds in surgical wards for years, great improvement was found, and entirely without any digestive troubles; nor does it produce any increase in the acts of urination. Administration by the mouth was found to be preferable to injections. Professor Bouchard said, in referring to this matter, that, finding the dose of

one and a half grammes was not enough, he had given up to five grammes, in order to obtain pure urine, free from pus, and always found the medicament to be quite inoffensive. He constantly gave it as an intestinal antiseptic, without any accidents. It is but little absorbed into the system, but is eliminated as a naphtil-sulphate of sodium, which is antiseptic and not at all toxic. In the treatment of cases of cystitis, he thought that injections of the naphtil-sulphate of soda might be substituted for the administration of the naphthaline by the mouth.

To continue therapeutical subjects, Drs. Pauly and Mondot, of Oran, in Algeria, publish a method of treatment in diphtheria which they claim has met with great success. Notwithstanding the fact that Algeria has a fine healthy climate, as a rule (something like Florida), diphtheria is endemic in several points, of which Oran is one. After detailing the fact of their want of success with all the various sprays and inhalations which had been recommended, the doctors thought that they only seemed to carry off little by little all the oxygen of the air of the sick-rooms, which were mostly heated to about 20° C. also: so at first they advised airing and cooling the chambers, and even changing the patients from one room to another during the day. Finding that this seemed to do good, they went further in the oxygenation of their clients, and sent them out of doors, even to the environs, and preferably where there were strong currents of pure air. (It must be remembered that the climate is very fine in Oran.) Their treatment may be formulated in brief thus:

1. Saturate the patients with plenty of pure fresh air, constantly renewed, by walking, riding, or otherwise.

2. Give sulphate of quinine, in doses of two or three decigrammes, twice or thrice a day, in coffee.

3. Paint the throat with such lotions as this:

℞ Sodii boratis, 5 grammes;
Acid. salicylic., 2 grammes;
Glycerin. (puræ), 50 grammes;
Aquæ destillatæ, 100 grammes. M.

S.—Apply four times a day upon a piece of lint or absorbent cotton.

4. Alimentation to be very simple. Milk, soups, soft-boiled eggs, etc., according to the appetite of the patient.

5. As the stomach and the whole digestive tract is mostly out of order, and as it will receive an accumulation of false membranes, drawn down by the movement of deglutition, use as an intestinal disinfectant sulpho-carbonated water.

Messrs. A. Cahn and E. Heppe, two assistants in Kussmaul's clinic in Strasbourg, have been successful in finding a new antipyretic, antifébrine. This body is indifferent, being neither an acid nor a base: its chemical composition differs from all the other antipyretics. It is a white powder, crystallizable, without odor, slightly bitter in taste, almost insoluble in cold water, but dissolves in all alcoholic liquids. Given by the mouth, it does not cause any disturbance of the digestive functions or any unpleasant symptoms. The dose given is twenty-five centigrammes, in cachets, or in wine: not more than two grammes has been given in the twenty-four hours. It is found to be four times more active than antipyrine, so that the same effect is produced with twenty-five centigrammes of it as with one gramme of antipyrine. The antipyretic effect commences within an hour after its administration, and attains its maximum in about four hours, when it persists, according to the dose given, from three to ten hours. After every dose the febrile temperature descends to normal or below it, and a considerable diminution is noticed in the frequency of the pulse. During this period the appetite often comes back, with an intense thirst and an augmentation of the urinary secretion. Not one of twenty-four patients who took it was affected with unpleasant symptoms; several among them, however, presented a certain degree of cyanosis of the face and extremities, which did not persist long.

Obstacles to Fecundation.—One of your late editorials on "The Causes of Female Sterility" induces us to try and present a résumé of Professor Pajot's lectures on "Des obstacles à la fécondation dans l'espèce humaine." The eminent veteran uses the plainest kind of language, as is his wont, but the importance of the subject, with the new and valuable ideas of treatment which he gives, will justify a modified version of his lectures, even in the cruder English, which does not lend itself so well to explain delicate questions as does the original French. He says, in substance, "Gentlemen, allow me in these last days of this session to study with you an important subject that is so often put on one side by medical men, to the great profit of idiotic superstitions and those industrials of both sexes who ornament the pages of newspapers with their sure cures of sterility, which I wish to speak about. Among the obstacles to fecundation in the human race the first rank must be given to a catarrhal state of the uterus, as it is the most common of all. Of twenty couples who consult you because the wife is sterile, ten or twelve of the women will have a catarrhal affection, more or less pronounced; some having only a small cork of mucus in the os uteri, which, however, closes it effectually and is very difficult to extract. Another obstacle is the narrowness of the external orifice of the neck: it is not so well known as it should be that in these cases there is usually a peculiarity of form, being cone-like in shape, with a very small orifice: we call it a 'top'-shaped os.

"The third most frequent obstacle is the

one most talked of by charlatans and ignorant medical men,—I mean uterine deviations. You know these all by name at least. For our present purpose we will make two great classes which differ as obstacles to fecundation: they are versions and flexions. Versions are of four kinds; flexions ditto, which I shall not dwell upon. The normal uterus presents a certain degree of anteversion nearly in the axis of the superior strait. If this is exaggerated, there is an anteversion; the contrary state is retroversion, and the lateral incline is lateroversion. Pregnancy brings a right lateroversion, the neck being on the left side. Flexions are much the same in name; but it is curious that the versions are greater obstacles than the flexions. A few years ago a lady came to me who had consulted Krassowsky in St. Petersburg, Scanzoni at Wurzburg, Braun at Vienna, and Bennett in England, who all told her that the position of her organs was such that she could not have any children. Scanzoni alone had said that it was not impossible. Upon examination I found a retroflexion so excessive that the base of the uterus was lower than the neck. I could put my finger in the angle that formed the flexion. I asked if the menstrual flow was regular. She answered yes. Reasoning that if it could come out, something might go in, I concluded that it was not impossible that she could become pregnant. Some four months afterwards I was suddenly called to this patient, who told me that she had not seen her courses since, and that on ascending the stairway that evening she had felt something give way inside, and went to bed in haste. I examined, and found the uterus nearly in its normal situation, and the result proved that she was pregnant. This case proves how careful we must be in such examinations. Suppose that I had used a hysterometer? I observed to myself, Here is a good chance to cure this lady of her retroflexion. The uterus is upright; keep it so. So I kept her in bed nearly three months after her confinement, and after the return of the courses ordered injections of tannin, etc. But, alas! she returned to me in a year with a retroflexion as bad as ever, which did not prevent her, however, from having three other babies. This shows the uselessness of rings and 'sachets,' etc., that are so much introduced to cure such people. That certain kinds of apparatus may give comfort is possible, but as to real cures they are all useless. I don't speak at present of prolapsus. We don't cure these deviations, because they are not maladies: they are infirmities. These women are no more ill than a person who is left-handed, unless there is also a catarrhal state, or a congestion, or an ulceration. Many women have a deviation without knowing it. It certainly very often constitutes an obstacle to fecundation,—one reason being that the *cul-de-sacs* formed make a false route for the male organ and complicate the difficulty of fecundation.

"Acidity of the vaginal mucus seems also to be a cause of the rapid death of spermatozoa. Finally, when I first began to teach, like those who preceded me, I said that, out of a hundred, ninety-nine times sterility was the woman's fault, and only one the man's. But during these last twenty-five years I have arrived at a very different result, which will astonish you as well as it did me. More than ten years ago I found the proportion of husbands who were the obstacles to fecundation rise to seven in eighty cases. I have seen in late years some four hundred cases in which I examined the seminal fluid, and I can now say that of one hundred cases, after two to twelve years of marriage, there were nearly twenty in which the husbands were at fault and the cause of the sterility; and I think when some thousands of cases will be collected that twenty-five per cent. will be reached. Don't fancy that it was alone in feeble men that the difficulty resided; not at all. Strange as it may sound, there are a large number of strong men who have no spermatozoa or have them in an imperfect state; and yet they fulfil the conjugal function perfectly well. One of my latest patients was a colossal man, with a head like a lion, who brought his wife to me complaining that the little woman was no use as to conception. Upon examination, I found her organs and functions in perfect order; and, taking the husband aside, I explained to him what I wanted. Under the microscope I found that there was not a single spermatozoon in it; not one. On questioning him, I found that his desires were ample, and in regard to previous ill health he could only recall a slight orchitis at seventeen years of age. Another patient was a short man who did not present anything particular in his appearance except broad shoulders. His wife was a tall, handsome blonde. They had the same complaint: no children. Examination of wife showed vagina and neck of uterus full of mucus. Examination of husband's spermatic fluid gave a result of millions of spermatozoa, thus reminding me of the extravagant boasting of the Gascon and the Marseillais. The first said that in his rivers there were so many fish that all you had to do was to dip up a bucket of water, and you could get all you wanted. The second replied that in the river in his country it was all fish and no water at all. Between these two extremes there are all sorts of cases. But it is not sufficient to have a certain number of spermatozoa. Professor Duplay has shown that they exist in quite old men, but they are smaller, and not active; and I contend that fecundation is not possible with such spermatozoa. In making an examination for size, always use the *same power of microscope at first.* This is important, so that you may be able to judge.

*

The smaller deformed ones oscillate some, but they are not half as long nor as large as they should be. There are exceptions to every rule, but usually they cannot fecundate. It is your duty to see to this matter. In those who have none at all, cure is almost hopeless; but those who still have some may be improved by treatment. It is possible that on the female side likewise some ova cannot be fecundated; but of this we know very little. But let me go on to treatment. For the catarrhal states, use emollient injections for the first few days, to allay any congestion, and then during the intermenstrual period—that is to say, not less than ten days nor more than fifteen after cessation of the menses—practise internal cauterization of the uterus, both the cavity of the neck and the body. Use for this purpose my porte-caustic mounted on very flexible whalebone, that cannot perforate the uterus. Professor Richet uses a solid metal one; but in his hands any instrument will do: don't fancy it would do so well in yours. Place powdered nitrate of silver in the little cup, close it with some unguent, and penetrate slowly into the uterus, empty the cup, and the operation is over. If you still fear the porte-caustic, use these little whalebone sticks, which are mounted solidly with a little cotton, carefully wipe out the mucus to get at the real surface, wet the cotton with a little water, and rub it in powdered nitrate of silver, forming a sort of paste, which you can paint over the surface easily. Keep the woman in bed three days or more, and continue emollient injections, and follow them with astringent ones. As to the narrow conically-necked uterus, the best treatment is *dilatation*. I do not believe in Sims's American divider, composed of two blades that are introduced, opened, and drawn towards you, as I have seen fatal results in two cases from its use. No; dilate gradually and largely the *external* orifice only; for, as the other gives passage to the menstrual flux, it will allow the spermatozoa to pass.

"I wish now to teach you some therapeutical measures that I think have never been mentioned by any one. When you are advising a woman who has a deviation, see the husband apart. If she has an anteversion, tell her to prepare for the sexual act by not urinating for five or six hours beforehand, if she wishes to have children. If it is a retroversion, advise as follows. After the monthly period she must eat plenty of eggs and rice, and take a small pill every evening for three or four days (the pill is simply two and a half centigrammes watery extract of opium). During these days she must resist defecation and perform the sexual act. This advice is based on anatomical and physiological facts, and will often succeed in removing these obstacles to fecundation. In one case the full bladder pushes the body of the uterus up, and in the second the full rectum corrects the deviation for the moment." To give further indications, the professor related the case of a patient who had a left lateroversion, making one of the false routes he talks of. Upon questioning the husband adroitly, he found that the conjugal act was performed in the usual classical manner,—dorsal decubitus, in fact,—and advised a change by placing the wife on her right side: conception followed, and the woman had eventually five other children.

With these different methods he also advises sterile people to have connection *only* about the menstrual period, a few days before and after, and never at other times. As to the husbands with no spermatozoa or with insufficient ones, he advises gymnastics, fencing, swimming, velocipedes, walking, etc., exercise of the inferior members, good living, and continence.

THOMAS LINN, M.D.

September 18, 1886.

BALTIMORE.

THE American Gynæcological Society had a successful meeting in this city during the past week. The attendance was fair, many of the papers valuable, and the discussions interesting. Some of the views expressed upon the removal of the uterine appendages seemed rather advanced to conservative outsiders, and appeared to strike some of the Fellows likewise. That a patient shall decide whether she will be desexualized may be sufficient to warrant metropolitan gynæcologists in removing the ovaries, but physicians generally should protest against such a monstrous doctrine.

The Fellows were entertained at dinner by the Baltimore Obstetrical and Gynæcological Society, and elaborate lunches were served at the residences of each of the Fellows belonging to this city. The visitors appeared to be well pleased with the hospitality shown them by the local profession.

To judge from the majority of those in attendance, physical beauty is not a necessary attribute of the successful gynæcologist.

At the meeting of the Medical and Surgical Society last Thursday, an interesting case of symmetrical gangrene of the toes was exhibited by Dr. Shertzer. The patient was a well-nourished man, 55 years of age. About a year ago the second toe of the left foot became affected. There was at first burning and redness, followed by superficial sloughing. The third toe of this foot and the second and third toes of the right foot were attacked later. In the discussion which followed the presentation of the case, the question was raised whether it was a case of Raynaud's disease, or one of ordinary gangrene consequent upon degenerative changes in the blood-vessels.

At the same meeting, Dr. T. B. Evans related two cases of aggravated dropsy with albuminous urine, which were promptly relieved by the administration of five grains each of iodide of potassium and chloride of ammonium. The exact cause of the dropsy was not ascertained.

Dr. Rohé also reported his experience with electrolysis in the removal of hairs, warts, moles, lupus, superficial epitheliomata, and other morbid growths of the skin. During the past year he had by this method successfully removed fifty-eight warts, fifty-six moles, some of them of considerable size and studded with coarse hairs, three vascular nævi, two fibroids about the size of a small cherry, two enlarged sebaceous follicles, one papilloma of the tongue, and one superficial cancer of the nose. He had also treated with encouraging success one case of lupus and three of acne rosacea by the same method. Dr. Rohé anticipates for electrolysis a large field of usefulness in the removal of neoplasms and infiltrations in the deeper tissues, as well as of the skin.

The medical schools will reopen for the winter session next Monday. The prospects are that the classes at the different schools will be about the same as last year.

The profession here has met a serious loss in the death of Dr. William M. Kemp, which occurred a few weeks ago. Dr. Kemp was one of the representative physicians of the last generation, and, when in his prime, wielded considerable influence in the community. For several years he had been in feeble health, and during the last twelve months had been confined to his bed. He was seventy-three years old at the time of his death.

G. H. R.

Baltimore, September 27, 1886.

PROCEEDINGS OF SOCIETIES.

THE AMERICAN GYNÆCOLOGICAL ASSOCIATION.

THE Eleventh Annual Meeting was held in the hall of the Johns Hopkins University, Baltimore, Maryland, September 21, 22, and 23. Morning and afternoon sessions were held each day.

Thaddeus A. Reamy, M.D., of Cincinnati, President of the Association, occupied the chair. The papers and discussions were almost exclusively upon questions relating to therapeutics and the problems of clinical gynæcology, and in consequence a large attendance of visitors was obtained. The following Fellows of the Association were present: Wm. H. Baker, Boston; Fordyce Barker, New York; Robert Battey, Rome, Georgia; B. B. Browne, Baltimore; Samuel C. Busey, Washington, D.C.; John Byrne, New York; James R. Chadwick, Boston; Thomas M. Drysdale, Philadelphia; Thomas Addis Emmet, New York; George J. Engelmann, St. Louis; Walter R. Gillette, New York; William Goodell, Philadelphia; William T. Howard, Baltimore; James B. Hunter, New York; A. Reeves Jackson, Chicago; Charles Jewett, Brooklyn; Joseph Taber Johnson, Washington; Chas. Carroll Lee, New York; Matthew D. Mann, Buffalo; William H. Parish, Philadelphia; Theophilus Parvin, Philadelphia; Thaddeus A. Reamy, Cincinnati; John C. Reeve, Dayton, Ohio; Wm. L. Richardson, Boston; John Scott, San Francisco; Alex. J. C. Skene, New York; R. Stansbury Sutton, Pittsburg; Ellwood Wilson, Philadelphia, and Henry P. C. Wilson, Baltimore.

First Day, Morning Session.—After the formal opening, with the calling of the roll, Dr. H. P. C. Wilson, on behalf of the resident Fellows, delivered a brief address of welcome.

The scientific work of the meeting was to have been inaugurated by Dr. Ellwood Wilson, of Philadelphia, but, as he had been called away unexpectedly, the President called for the reading of the next paper on the programme, by H. P. C. Wilson, of Baltimore, on

THE DIVISION OF THE CERVIX BACKWARD IN SOME OF THE FORMS OF ANTEFLEXION OF THE UTERUS WITH DYSMENORRHŒA AND STERILITY.

The want of judicious selection of cases, the unskilful performance of the operation, and the improper treatment after it, have caused a procedure which was endorsed by such men as Sims and Simpson to be barren of good results and prolific of bad in the hands of many practitioners. It has shared the fate of many valuable remedies and many new operations, and has fallen into undeserved neglect, once again proving that the abuse of a thing is no argument against its proper use.

The cases for which the lecturer especially recommended this operation were—

1. Those of anteflexion of the uterus with an elongated indurated cervix, where the body is bent upon the neck, or the neck upon the body, or where they are bent upon each other, thus forming a more or less acute angle at the interval.

2. Cases of not such acute flexion, but where the cervix is hyperplastic and indurated, as blue as a mulberry and as dense as cartilage.

3. Cases where there is a hard and unyielding band encircling and constricting the internal os, through which the probe passes with difficulty, and gives to the hand the sensation as if it were passing over rough and dense cartilage, while the finger of the other hand in the sulcus between the body and the neck, in front, gains the impression of

there being a cord strongly tied around the uterus at the point of union between body and neck.

The conditions described as in the third class are frequently found also in the first, and are occasionally present also in the second; and in typical cases of anteflexion of the uterus, where the knife should be used in preference to other remedies, all of the lesions above described are coexisting.

Nearly all such cases are sterile. The very rare exception proves this rule. In all these cases we find the Nabothian and utricular glands hypertrophied and indurated, so that the probe in passing from the external os along the cervical canal, and through the internal os into the cavity of the uterus, feels as if it were passing over the surface of an Osage orange instead of that of a soft and pliant mucous membrane.

With regard to the use of dilators or treatment by divulsion, he maintained that no dense, unyielding cervix should be forced open: if so, it will be done with far greater hazard than could accrue from a clean incision with a sharp knife and scissors. All accidents from cutting are the result of improper after-treatment. Accidents from forcible stretching are the immediate results from the force employed. Accidents from tents, plugs, and stems follow from septic poison, or long-continued irritation of an organ naturally rebellious to foreign bodies within its cavity. Of all these the tents are the most dangerous. We had better cut again and again than to use these harsh means, advocated by some, to dense and unyielding tissue, when the uterus is flexed and the internal os stenosed so that the smallest probe enters with difficulty, while dysmenorrhœa and sterility are present. He had perfectly cured several such cases, where they had previously borne children, by cutting the cervix backward and the internal os backward and forward. The bilateral incision of the cervix would not improve such a case: its second state would be worse than the first.

To overcome the diseased condition of the endometrium observed in these cases, it is not only necessary to relieve the stricture at the internal os, but also to straighten the organ, or at least to give a free and straight outlet from the uterine cavity. No pessary for anteflexion will relieve a condition such as this.

Before incising the cervix, any existing cellulitis should be removed by appropriate treatment, and after the operation the patient should be allowed to recover fully (which usually requires about a month), and then be allowed to go home and rest for another month without interference, before the subsequent treatment by dilatation or intra-uterine applications is attempted. The too early resort to after-treatment is the cause of many failures and bad results. The best application for the diseased endometrium is Churchill's tincture of iodine, to be applied to the interior of the uterus. The clinical records of several cases in which highly-successful results were obtained concluded the paper. He had performed the operation about five hundred times without losing a patient by death: in one pelvic cellulitis was set up, and she nearly died from injudicious after-treatment. Since then he interferes very little, and leaves them alone, almost absolutely, for two months after the operation.

Dr. T. A. EMMET, in response to an invitation from the chair, opened the discussion. Fifteen or twenty years ago he would have been willing to subscribe to everything that had been said by the reader of the paper. He had no doubt, speaking personally, that he had done as much harm as anybody by this operation, and the results that he had obtained had led him to change his mind with reference to it. In any discussion of this question we must separate sterility and dysmenorrhœa, which are due to different causes.

Mechanical dysmenorrhœa he regarded as a myth. Dysmenorrhœa depends upon faulty nutrition. Patients suffer with dysmenorrhœa when the cervical canal is entirely unobstructed. The cases for which the operation has been recommended may be divided into two classes:

1. Hypertrophic elongation of the neck of the cervix, in which sterility and dysmenorrhœa may both exist.

2. Cases of flexure of the uterus, which, according to his experience, were always due to some inflammation around the uterus, or affecting neighboring structures, and which brings it down. In these cases, if the patient submits to the operation, no good is done by it.

In the first class dysmenorrhœa precedes the appearance of the menstrual flow, and in the second it does not commence until after menstruation commences, and persists after its cessation. In congenital cases of elongation of the neck of the cervix, with induced flexion, he occasionally operates with good results. The second class may be accompanied by leucorrhœa and other disorders, but the real source of the trouble is outside the uterus. Painting the canal will therefore do very little good. He had known of twenty deaths from the operation defended by the speaker; but if the precaution be observed by all who perform the operation to remove all cellulitis as a preliminary, they will do good, but not by the operation. Even in the first class he rarely operates where the flexure is above the vaginal junction. After denuding the cervix, he showed how a covering of mucous membrane might be made for it by sliding it from the vagina by a plastic operation.

Dr. CHADWICK approved the remarks of the preceding speaker. He recognized only

one form of flexion, and would not divide it into flexion of body and of neck. Anteflexion is always congenital, and is usually due to lack of development of the uterus, and probably of the associated organs. Therefore, in cases of congenital flexion, he did not consider that he had the uterus alone to deal with. This is why we are so rarely successful in removing sterility and dysmenorrhœa by operation. It had succeeded in some cases in his hands when the external os had been very small. Operation should be only performed when the uterus is well developed in every other respect. When dysmenorrhœa is due to congenital defect of development, the fault may extend throughout the whole system.

Dr. BAKER congratulated the lecturer upon his success, and attributed it to his great care in the after-treatment. One thing which had not been alluded to was the danger of hemorrhage after the operation. He had seen such a case in the hands of Marion Sims, and had one of his own. The paper is valuable as a contribution to the surgical treatment of the disorders named, and helps to decide the question when it should be done and when it should not be done.

Dr. BARKER referred to the early history of the operation, and its frequent performance by Simpson, which he witnessed while in Edinburgh. He had brought back with him Simpson's instrument, which was the first one of the kind in this country. He was astonished at seeing Simpson operate in his office and let the patients go home after it; but in reply to his question he was told that the surgeon had never seen any severe hemorrhage from the operation. He learned, however, that Simpson lost two cases from hemorrhage during the same year, after he left. After his return he operated for sterility upon a patient with stenosis, but no flexion, who had been married fourteen years, and she subsequently became pregnant. He also showed the instrument to Dr. Sims, who, with his usual genius, invented many improvements upon it. After performing the operation many hundreds of times, he had ceased to operate years ago, being dissatisfied with the results. Until Dr. Emmet spoke, however, he had been unaware that there had been so many deaths from the operation.

Dr. SCOTT recommended that immediately after the operation a tampon of cotton tinctured with iodine solution be placed against the raw surface, in order to prevent suppuration, and the patient kept in a state of absolute rest in bed. He seldom performs the operation, and always under certain restrictions, and with the precaution named in order to avoid bad results.

Dr. HOWARD had been led to the conclusion that for cases of dysmenorrhœa and sterility no one form of treatment will answer. Dr. Sims complained to the last days of his life that surgeons did not discriminate. He prefers the bilateral incision where the uterus is symmetrical and where he operates merely to widen the canal; in other cases he uses the antero-posterior incision. His rule is to treat these cases first in accordance with the teachings of the therapeutic school of gynæcologists, at the head of which stands Dr. Barker, before resorting to surgical measures. The statement of Matthews Duncan, that the descriptions of mechanical dysmenorrhœa were "mere garrulity," he was not prepared to accept. With regard to the reported bad results from the operation, he asked what operation is not, at times, followed by bad results? We should not reject an operation because the results are not uniformly good, but should endeavor to learn its limitations. With our present improved methods we should obtain better results than ever before. After operating under antiseptic precautions, he introduces an ebony plug in the cervix with a light tampon, and leaves it undisturbed for four or five days, by which means the treatment is considerably shortened. He had had one case of death after divulsion.

Dr. H. P. C. WILSON had heard nothing in the discussion that would convince him that, in properly-selected cases, division of the cervix is not the best operation to perform. At the same time, he always warns patients that unless they can give the proper care to after-treatment the operation had better never be performed. When the hypertrophied neck of the uterus is bent almost parallel with the body, he maintained that the discharges were retained during the inter-menstrual period, and they become acrid and remain there month after month until labor-pains come on, which expel the accumulated secretions. When the uterus is bent upon itself, the canal is closed and obstruction exists. The only treatment is to open the canal by antero-posterior incisions, and make the canal pervious. Where the operation fails, it is due to want of proper after-treatment. In his present treatment he does not pass a probe until two weeks have elapsed since the operation.

With regard to Dr. Scott's suggestion, he believes that the best thing to use to prevent infection is a solution of carbolic acid, glycerin, and iron. He preferred that the cervix should bleed after the operation, and he then avoided possible septicæmia by plugging the vagina with the iron solution.

The object of the paper was to discuss the comparative value of division and divulsion of the cervix in the treatment of certain cases of anteversion with stenosis. To his own mind there was no comparison between the two: he believed that the danger to the patient from the former does not begin to compare with that from the latter.

ANOTHER MODIFICATION OF EMMET'S CERVIX OPERATION, WITH A CASE IN POINT,

was the title of a paper by R. STANSBURY SUTTON, M.D., of Pittsburg, Pennsylvania.

Some cases of lacerated cervix present peculiarities which make some modification of Emmet's operation a necessity. Last year the speaker reported one such expedient; this year he had devised another. In a patient presenting a torn cervix of almost cartilaginous density, and with the angles filled with hyperplastic tissue, he performed the following operation. Thrusting one blade of a pair of strong scissors into the cervical canal, the cervix was divided antero-posteriorly. With a double-edged knife the four surfaces were pared, except that a strip of mucous membrane was left on each side, so that when brought together these secured a patulous cervix.

Dr. EMMET thought the operation ingenious: its value could be tested only by experience. As a rule, where there is much old cystic degeneration and hypertrophy, he would do just as he would in a case of enlarged tonsils,—amputate; and he then would cover the stump with vaginal mucous membrane.

Dr. ENGELMANN believed that a piece of catgut would preserve the canal as well as the strip of mucous membrane. The modification did not seem to him to be very different from that proposed by the same speaker last year. Referring to Dr. Emmet's remarks, he called attention to the fact that in Germany what is known as amputation of the cervix is not exactly what we understand by it.

Dr. BAKER urged the importance of preliminary treatment and the preservation of mucous membrane. His own modification was the cutting of a "V"-shaped piece of mucous membrane and covering the wound with it, thus preventing rolling outward. He thought the operation of Dr. Sutton ingenious and likely to be of service.

Dr. ENGELMANN defined amputation as merely the removal of diseased tissue. When this operation of Dr. Sutton's is called for, the parts are very thoroughly diseased and degenerated, and there is no healthy mucous membrane left.

Dr. DUDLEY asked how the sutures were to be introduced.

Dr. CHADWICK. One of the speakers has referred to the fact that amputation of the cervix means something different in Germany from what it does here. He learned that at Schroeder's clinic it was about what we call Emmet's operation, the result being the same.

Dr. SUTTON. The operation was suggested by the character of the case. If in a given patient you can do what is aimed at in Schroeder's and Martin's operations, by removing a wedge-shaped portion of cervical tissue and doubling it in so as to turn inside what before was outside, that is good; but, as in the case reported, where you have either to cobble out a cervix or leave it alone, you cannot do the ordinary operation. He believed that the mucous membrane is not absolutely diseased, and that in the course of time it will become healthy mucous membrane. With regard to the introduction of the sutures, their position can be seen in the diagrams: no particular mechanical skill is required to introduce them so as to produce a good cervix.

A paper by ELLWOOD WILSON, M.D., on

THE TREATMENT OF LACERATIONS OF THE CERVIX UTERI,

was read by the Secretary.

In this communication the writer called attention to a new treatment of cases of laceration of the cervix, where the wound is recent. He had found nothing better in many cases of old laceration than Emmet's operation, which he valued highly, but thought that it was performed in some cases to which it was not suitable. Where after delivery laceration of the cervix exists, he recommended the use of irrigation with mercuric chloride solution on every second or third day, with antiseptic napkins, and cervical suppositories, or bacilli, containing iodoform. In the course of ten or twelve days after delivery another examination is made, and a solution (ʒj to ʒj) of nitrate of silver painted over the surface after it has been cleaned. This can be repeated every four or five days until it heals up. Several cases were reported in illustration.

Dr. BAKER approved the recommendation of the lecturer to defer the treatment until some days have elapsed after delivery. He strongly deprecated operative interference until the patient recovers from the exhaustion of confinement. In his own experience he had never seen a case which had required a second operation until within the last year, while those operated on at once very frequently require another operation.

Dr. EMMET believed that the only excuse for surgical interference immediately after labor is where hemorrhage is present with recent laceration. It is not in all cases in which it exists that a fissured cervix gives trouble. He thought that in all cases in which laceration of the cervix had given trouble it was owing to septic poisoning. He believed that many lacerations heal of themselves, and thought that with hot-water injections Dr. Wilson would have obtained just as good results as from the silver salt.

Dr. SCOTT reported one case of immediate operation, with a successful result.

Dr. BAKER reported the only primary operation of this kind which he had ever performed. In a case of forceps-delivery, of face-presentation, and the occiput backward (the only case of this character that he had ever seen born alive), the cervix and perineum were both torn, and he operated upon

both without delay. The patient made a good recovery; the stitches did not tear out, but the patient was very sick. It is significant that among forty-one cases of puerperal fever, which was epidemic in New York last spring, six had suffered a laceration of the cervix, which had been at once sewed up, and only one of these showed complete union.

Afternoon Session.—T. ADDIS EMMET, M.D., read a paper entitled

PELVIC INFLAMMATIONS. CELLULITIS *versus* PERITONITIS.

The dangers of limited inflammations of the peritoneum, the frequency, and the difficulties in the way of diagnosis, were dwelt upon in connection with disorders of the pelvic viscera. Cellulitis commonly accompanies peritonitis, but it is not of much importance unless associated with the presence of foreign microbic organisms. When the inflammation stops before producing pus and forming abscesses, the products may be completely absorbed. Where pus has formed, adhesive inflammation occurs, with subsequent cicatricial contraction.

In conclusion, he referred to the production of pus in the Fallopian tubes and ovaries as one of the results of gonorrhœa, and deprecated the frequency with which these organs are removed at the present day. He believed that if the true mortality of this operation were known it would appall the profession; although in New York it is performed with as good results as anywhere. It should be done only as a last resort, after therapeutic means have been faithfully employed without relief. If performed without proper restrictions, the good name of the profession is bound to suffer. He condemned laparotomy for diagnostic purposes, and the sacrifice of the whole of one or both ovaries when only a part is diseased.

Dr. BATTEY looked at the shield from the other side than that seen by the lecturer. His observation had shown him that pelvic inflammations commence very commonly in diseased ovaries. In a private letter to him, Dr. Emmet said that in his early life he had found a number of cases with ovaries in a state of cystic disease due to inflammation, in which he could find no symptoms during life to correspond with the decided condition of disease.

With reference to the frequency of abdominal operations at the present day, he was very much of the opinion of the lecturer, that they are done too frequently. A short time ago a general practitioner expressed great umbrage because he had returned a case which had been sent with a request for operation, because he did not regard it as a suitable one. It is not every case of organic disease of the ovary that requires this mutilation of its owner. He recalled a case of a young woman under his care in the Infirmary some years ago with large ovaries, which he advised her to have removed. She refused to permit the operation to be performed, and she afterwards recovered, married, and has borne two children, and is in good health. He had seen one or two other cases in which operation had been advised, but not performed, and the patients afterwards bore children. He was therefore not prepared to say that all cases of diseased ovaries should be operated upon.

Dr. BARKER requested the speaker to state succinctly the grounds which to him would justify the operation.

Dr. BATTEY replied that each case must be considered for itself. A poor woman in the mountains of Georgia, who is rendered a hopeless and helpless invalid by disease of the ovaries, and who by the removal of the ovaries will be restored to health and usefulness, would be a proper case for operation in Georgia; but at the same time if she lived in New York, with all the comforts and resources of a private hospital at command, the same kind of a case might be saved without an operation. In either case all ordinary means in our power should be used for relief before resorting to operation. This commends itself to his judgment and his conscience. He does not insist that there shall be always an exact diagnosis of the condition of the ovaries and tubes: it is sufficient to know that the patient is worn out and utterly miserable from faulty performance of function, and he extirpates the ovaries. Observation has shown that in these cases the ovaries are commonly diseased. The operation is justified by its results. The reply to the question would be the same as that made a few years ago: "I remove the ovaries when the general health of the patient is broken down and destroyed and I can see no other hope of restoration by any known means, and where I do see a reasonable hope of recovery as a result of the operation."

Dr. BARKER congratulated himself upon having certain points made clear, and thought that the preceding speaker had laid surgical gynæcologists and the ranks of suffering women under obligation, in stating that he did not wait to make his diagnosis until he opens the patient's abdomen.

Dr. SUTTON believed that when an ovary is diseased and cannot be cured by medical means, and it is interfering with the health of the patient and her duties in life, it should be extirpated. He agreed with the reader of the paper that laparotomy is performed too much; not that it is done too much by competent men, but it is done too much by incompetent men. It would have been far better if Tait's statistics had never been published. It is not always possible to make an exact diagnosis before opening the abdomen, nor

is it always easy afterwards. (Several specimens were shown illustrating difficulties of diagnosis.)

Dr. BUSEY referred to the histological analogy existing between serous membrane and cellular tissue, and claimed that the affections named should be included under one head,—pelvic lymphangitis. He hoped the time would come when we could have some surer guide to the limits of usefulness of the operation than moral or social considerations and the general appearance of the patient.

Dr. SCOTT reported several cases of successful operation.

Drs. MANN and H. P. WILSON concurred in the sentiments of the paper.

JOHN C. REEVE, M.D., of Dayton, read an interesting account of

A CASE OF ABDOMINAL SECTION FOR CHRONIC SUPPURATIVE PERITONITIS,

followed by a successful result, except that a fæcal fistula had formed, pus having been discharged per rectum prior to the operation.

A general discussion took place upon the operation, in which Dr. SCOTT, Dr. GOODELL, Dr. C. C. LEE, Dr. R. S. SUTTON, and Dr. J. T. JOHNSON participated. Dr. REEVE then made some concluding remarks.

The Society then adjourned, to meet the following morning.

The Baltimore Gynæcological and Obstetrical Society gave a reception and banquet to the Association in the evening, at Rennert's Hotel.

Second Day, Business Session.—The following officers were elected:

President.—A. J. C. Skene, M.D., Brooklyn.

Vice-Presidents.—J. C. Reeve, M.D., Dayton, Ohio; Ellwood Wilson, M.D., Philadelphia.

Secretary.—J. Taber Johnson, M.D., Washington.

Treasurer.—M. D. Mann, M.D., Buffalo.

Members of Council.—W. H. Baker, M.D., Boston; F. M. Drysdale, M.D., Philadelphia; C. C. Lee, M.D., New York; A. Reeves Jackson, M.D., Chicago.

The next place of meeting, New York; time, September 15, 1887.

With regard to the proposition to co-operate in the movement for confederation of the various special societies, it was received, and, on motion, delegates were appointed to express favorably the sentiments of this body at the convention called for September 24, 1886.

(To be continued.)

ANTIPYRINE NOT TO BE GIVEN IN PNEUMONIA.—Posadski reports a number of illustrations of the bad effects from antipyrine administered during the course of pneumonia.

MEETING OF COMMITTEES ON CONFERENCE OF VARIOUS SPECIAL ASSOCIATIONS REQUESTED TO PARTICIPATE IN A CONJOINT SESSION.

IN response to the notice issued by the Secretary of the Committee on Conference of the American Surgical Association, the several Committees on Conference met at the Army Medical Museum, Washington, D.C., at twelve o'clock noon, on Friday, September 24, 1886.

The meeting was organized by the election of Dr. S. C. Busey, of Washington, Chairman, and Dr. J. Ewing Mears, of Philadelphia, Secretary.

The Secretary reported that he had received notification of the appointment of the following Committees:

1. *American Ophthalmological Association.*—O. F. Wadsworth, M.D., Boston; C. T. Bull, M.D., New York; George C. Harlan, M.D., Philadelphia; Samuel Theobald, M.D., Baltimore; R. E. Freyer, M.D., Kansas City, Missouri.

2. *American Otological Association.*—C. R. Agnew, M.D., New York; H. Knapp, M.D., New York; John Green, M.D., St. Louis; W. H. Carmalt, M.D., New Haven, Connecticut; George Strawbridge, M.D., Philadelphia.

3. *American Gynæcological Society.*—S. C. Busey, M.D., Washington; Fordyce Barker, M.D., New York; J. R. Chadwick, M.D., Boston; J. Taber Johnson, M.D., Washington; Thomas A. Emmet, M.D., New York.

4. *American Laryngological Association.*—J. Solis Cohen, M.D., Philadelphia; F. I. Knight, M.D., Boston; G. W. Lefferts, M.D., New York; F. H. Bosworth, M.D., New York; E. L. Shurly, M.D., Detroit.

5. *American Dermatological Association.*—H. G. Piffard, M.D., New York; F. B. Greenough, M.D., Boston; R. B. Morrison, M.D., Baltimore; L. N. Denslow, M.D., St. Paul, Minnesota; G. H. Tilden, M.D., Boston.

6. *American Surgical Association.*—C. H. Mastin, M.D., Mobile; C. T. Parkes, M.D., Chicago; N. Senn, M.D., Milwaukee; J. Ford Thompson, M.D., Washington; J. Ewing Mears, M.D., Philadelphia.

7. *American Neurological Association.*—L. C. Gray, M.D., Brooklyn; J. Van Bibber, M.D., Baltimore; E. C. Seguin, M.D., New York; Wharton Sinkler, M.D., Philadelphia; Philip Zenner, M.D., Cincinnati.

8. *American Climatological Association.*—A. L. Loomis, M.D., New York; F. Donaldson, M.D., Baltimore; F. C. Shattuck, M.D., Boston; E. T. Bruen, M.D., Philadelphia; W. W. Johnston, M.D., Washington.

9. *Association of American Physicians and Pathologists.*—William Pepper, M.D., Philadelphia; Francis Delafield, M.D., New York; R. T. Edes, M.D., Boston; J. Palmer Howard, M.D., Montreal; J. T. Whittaker, M.D., Cincinnati.

The roll was called, and the following members of the Committees answered to their names:

1. Ophthalmological Association: O. F. Wadsworth, M.D., Samuel Theobald, M.D.
2. Otological Association: C. R. Agnew, M.D., W. H. Carmalt, M.D.
3. Gynæcological Society: S. C. Busey, M.D., J. R. Chadwick, M.D., J. Taber Johnson, M.D.
4. Laryngological Association: F. I. Knight, M.D., E. L. Shurly, M.D.
5. Dermatological Association: H. G. Piffard, M.D., G. H. Tilden, M.D.
6. Surgical Association: C. H. Mastin, M.D., J. Ford Thompson, M.D., J. Ewing Mears, M.D.
7. Neurological Association: L. C. Gray, M.D., J. Van Bibber, M.D.
8. Climatological Association: F. Donaldson, M.D., W. W. Johnston, M.D.
9. Association of American Physicians: William Pepper, M.D.

Dr. William Thomson, of Philadelphia, was present as a member of the Committee of the Otological Association, in place of Dr. George Strawbridge, who had resigned from the Committee; and Dr. W. Hendrie Lloyd, of Philadelphia, was present as a member of the Committee of the Neurological Association, in place of Dr. Wharton Sinkler, who had resigned.

On motion, it was resolved that the Associations represented should vote by title, taken in chronological order, and as a unit.

Dr. William Pepper offered the following resolutions, which, after careful consideration and discussion by those present, were adopted separately, and then as a whole:

"*Resolved*, 1. That it is desirable that the following Societies—the American Surgical Association, the American Ophthalmological Association, the American Otological Association, the American Neurological Association, the American Laryngological Association, the American Gynæcological Society, the American Dermatological Association, the American Climatological Association, the Association of American Physicians and Pathologists—shall arrange for a conjoint meeting in the city of Washington, in the month of September, 1888, and subsequently at intervals of three years, at the same time and place.

"2. That this arrangement shall not interfere in any way with the autonomy of each special Society; and that each Society shall retain the right to withdraw at any time from this conjoint scheme.

"3. That the special feature of the meeting shall be the conjoint assemblage of the special Societies on two evenings during the session; on one of which there shall be an address delivered by the President of the conjoint meeting, and on the other there shall be communications by a referee and a co-referee on some subject of general professional interest.

"4. That each special Society approving this report is invited to appoint one representative (with an alternate), and that the representative so appointed shall constitute an Executive Committee to serve for one year, with power to elect such officers for the first conjoint meeting as may be deemed necessary; to prepare a programme for said meeting; to make all other necessary arrangements; and to prepare and submit a plan of organization for future meetings.

"5. That all expenses connected with the conjoint sessions shall be apportioned equally by the Executive Committee among the special Societies participating."

Owing to the views entertained by the Committees of the Ophthalmological and Dermatological Associations with regard to the intervals of times of the meetings, they abstained from voting upon the first resolution.

The Secretary was instructed to send to the medical journals of the country a report of the proceedings of the meeting, a printed copy of the same to each member of each Association participating, and a certified copy to the Secretary of each Association.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held September 8, 1886, the President, JOHN A. WYETH, M.D., in the chair.

NOTABLE ATHEROMA OF THE CORONARY ARTERIES AND OF THE ARTERIES AT THE BASE OF THE BRAIN; FATTY PANCREAS.

Dr. LOUIS WALDSTEIN presented the specimens, which were interesting chiefly on account of the absence of symptoms pointing to disease of the heart. The patient had had diabetes and albuminuria. The autopsy revealed calcification of the coronary arteries in a marked degree, also of the arteries at the base of the brain. There was a less marked atheromatous change in some other portions of the arterial system. The man was very fat, and the pancreas was a mass of fat nearly throughout its entire extent. The liver was fatty and cirrhotic; the kidneys were large, and of a pale grayish-yellow color.

DERMOID CYST OF THE OVARY AND BROAD LIGAMENT.

Dr. EUGENE HODENPYL presented the specimen, which was removed from the body of a woman, æt. 45, who died of pneumonia. The uterus and left ovary were normal. The right Fallopian tube was elongated, measuring one hundred and thirty millimetres. The left ovary was enlarged, being forty-three millimetres in length and twenty-two millimetres in thickness. It was lower down in

the pelvis than normal. Occupying nearly the whole of its substance were three communicating cysts filled with a white, semi-solid material, composed of fat-droplets, epithelial scales, and a considerable number of short, fine hairs. The cyst-wall was formed of dense connective tissue. In the substance of the ovary were a number of very small masses of calcareous material. Within the folds of the broad ligament, and extending from its outer attachment as far as the uterus, was a multilocular cyst, which communicated with those in the ovary. It measured one hundred and twenty millimetres in length, forty millimetres in depth, and eighteen millimetres in thickness. It contained the same elements as the cysts of the ovary, but its contents were softer and darker in color, and the hair and epithelial scales were less numerous.

Dr. PRUDDEN had seen the specimens when fresh, and it was a question whether the two cysts were originally entirely separate.

URETHRAL CALCULI.

The PRESIDENT presented the specimens, which were removed from a man on whom he had operated for urethral calculi in 1882 and 1883. When the patient presented himself, some months ago, he found a calculus occluding the urethra five inches from the meatus. At the former operations he had divided urethral strictures, but he decided now to cut down upon the calculus directly from below. Two calculi were found in the urethra, and some small ones within the bladder. The patient had a chill, followed by fever and finally death. An autopsy was not obtained, but it was probable there was disease of the kidneys, of which there had been some symptoms.

REVIEWS AND BOOK NOTICES.

A REFERENCE HAND-BOOK OF THE MEDICAL SCIENCES. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Vol. III. Illustrated by Six Chromo-Lithographs and Seven Hundred and Eighteen Fine Wood Engravings. Edited by ALBERT H. BUCK, M.D. Supplied to Subscribers only. Price per Volume, Cloth, $6; Sheep, $7; Half morocco, $8. William Wood & Co., New York, 1886. Pp. 813.

The present volume of this splendidly-illustrated work of reference includes subjects from "Face" to "Hysterotomy." Among the articles most worthy of mention are those upon the "Face, Fascia, and Foot," by Frank Baker, M.D.; "Fever," by George B. Shattuck, M.D.; "Field Surgeons and their Duties," by Joseph R. Smith, M.D.; "Fingers, Contractions of," by W. W. Keen, M.D.; "Fœtus, Development of," by Charles S. Minot, M.D.; "Forceps," by Theophilus Parvin, M.D.; "Fractures," by Lewis A. Stimson, M.D.; "Fungi, Edible and Poisonous," by F. Peyn Porcher, M.D.; "Gangrene," by Surgeon John B. Hamilton, M.D.; "Gout," by Walter Mendleson, M.D.; "Growths, Pathological, or Tumors and Gumma," by W. F. Councilman, M.D.; "Gynæcological Examinations," by Henry C. Coe, M.D.; "Habitations," by J. Pickering Putnam, M.D.; "Hæmoglobinuria," by F. P. Henry, M.D.; "Hand," by Thomas L. Steelman, M.D.; "Hearing," by William Gilman Thompson, M.D.; "Heart," by various contributors; "Hernia," by Middleton Michel, M.D.; "Histological Technique," by George Cornell Freeborn, M.D.; "Hospitals," by Edward Cowles, M.D.; "Hygiene," by Medical Director Albert L. Gihon, M.D., U.S.A.; "Hypnotism," by H. Gradle, M.D.; and on "Hysterectomy and Hysterotomy," by Andrew F. Currier, M.D. The brief illustrated articles upon "Medical Botany," by W. P. Bolles, M.D., add greatly to the value of the work, which we commend to the examination of our readers.

A TREATISE ON ELECTROLYSIS AND ITS APPLICATIONS TO THE THERAPEUTICAL AND SURGICAL TREATMENT OF DISEASE. By ROBERT AMORY, A.M., M.D. Harvard. Illustrated by nearly One Hundred Fine Wood Engravings. Supplied only to Subscribers for "Wood's Library of Standard Medical Authors" for 1886 (twelve vols., price, $15), of which this is Vol. VIII. New York, William Wood & Co., 1886. 8vo, cloth, pp. 314.

On account of the prominence which electrolysis is assuming in therapeutics, there is felt in the profession generally a need for better knowledge of the principles and practice of this interesting and important department of electropathy. Dr. Amory in this monograph begins with a statement of the principles of physics as applied to electrolysis, and subsequently discusses at length the applications of these principles in the treatment of disease, explaining the various forms of apparatus, and their employment in a number of conditions. The author has succeeded in making a very useful book, which is clearly printed on good paper. The illustrations are excellent, some of them being from photographs of cases.

TRANSACTIONS OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA. Third Series. Vol. VIII. Printed for the College, and for sale by P. Blakiston & Co., 1886.

The present volume contains the papers read before the College from November, 1884, to June, 1886, inclusive, and discussions thereon, preceded by memoirs of Dr. John Light Atlee and of Dr. George Hamilton, and

lists of officers and Fellows. From a hasty review of its pages, we believe that in variety of subjects discussed in the papers, and in the high character of the papers themselves, the volume is one of the best that has been issued by the College, which will soon celebrate its centennial anniversary.

POCKET MEDICAL FORMULARY, ARRANGED THERAPEUTICALLY. By ALEXANDER HAZARD, M.D., and BERNARD M. GOLDBERG, M.D. Revised and Enlarged by ABRAHAM S. GERHARD, A.M., M.D., etc. With an Appendix containing Formulas and Doses of Hypodermic Medication, a Table of Eruptive Fevers, and Poisons, their Symptoms, Antidotes, and Treatment. Philadelphia, 1886. 12mo, pp. 434. With flap.

This is a very convenient hand-book, containing formulæ which have been recommended by various authorities for a large range of disorders. A running alphabet, in index form, at the side of the page, greatly facilitates reference. For students especially, the drug combinations and therapeutic suggestions contained in its pages will be found very valuable. Additions can be made upon blank pages which are interleaved.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY. AUTHORS AND SUBJECTS. Vol. VII., Insignarès-Leghora. Washington, Government Printing-Office, 1886.

The seventh volume of this great index-catalogue contains 14,688 authors and titles, representing 5987 volumes and 12,372 pamphlets; also 6371 book-titles and 34,903 journal articles. It also contains a list of abbreviations of titles of periodicals and collective works, used in indexing, which have been used in preparing all the volumes which have thus far been published. This will be found a great convenience to facilitate reference.

NEW REMEDIES AND CLINICAL NOTES.

THE TREATMENT OF ERYSIPELAS.—An interesting contribution to the treatment of erysipelas emanates from the University Clinic of Professor Kraske, of Freiburg, Dr. G. Kuehnast being the reporter, in No. 9 of the *Centralblatt für Chirurgie*.

Kuehnast formulates his views as follows:

1. The treatment of erysipelas by multiple scarifications and incisions, with subsequent application of carbolic acid, is the most effective method at our disposal.

2. The method is not to be recommended in cases of light erysipelas, and in cases of erysipelas of the face or of other exposed surfaces.

3. Certain modifications may be practised. Thus, in extensive erysipelas in decrepit individuals the scarifications may be limited to the margins where the process is progressive.

In children and old people it is advisable to substitute salicylic or boric acid for the carbolic-acid washings and dressings.—*Weekly Medical Review*.

RHEUMATIC HYPERPYREXIA.—Dr. H. Barnes, in a paper read before the Carlisle Medical Society, urges that in all cases of acute rheumatism, as soon as there is any indication of nervous symptoms, and particularly in patients of a high degree of nervous susceptibility, a careful watch should be kept on the temperature. Dangerous symptoms may be sudden in their onset, and drug treatment seems entirely to fail to arrest them. He recommends the application of cold when the temperature reaches 105°. The graduated bath is the method he most approves of, commencing it at 90° and gradually reducing it to 70°. As soon as the temperature is sufficiently lowered, the treatment should be suspended and the patient placed in warm blankets; otherwise dangerous symptoms of collapse may supervene.—*Edin. Med. Journ.*, June, 1886.

MISCELLANY.

THE CHARLESTON MEDICAL RELIEF FUND.—The announcement that "Charleston physicians are in great need," which was made immediately after the recent dreadful disaster by some of our well-meaning but impulsive contemporaries, was, we are glad to learn, exaggerated. While, as individuals, the members of the medical profession in Charleston, as a rule, neither need nor would accept pecuniary aid, the case is different with the Medical College of the State of South Carolina, which, we regret to see, suffered severely, and unless repairs are promptly made, which will require at least six thousand dollars, the school will be compelled to lose the winter session. Contributions should be sent to Middleton Michel, M.D., Charleston, South Carolina, either for the immediate relief of the families of the profession or for the rebuilding of the college.

OPIUM-GROWING IN THE UNTED STATES.—Last year an attempt at the cultivation of opium was made at New Ulm, Minnesota, by Mr. Emil Heschke. Several kinds of poppies were experimented with, and specimens of the *Papaver somniferum* were raised whose unripe capsules yielded opium containing fifteen and two-tenths per cent. of morphine. The Pharmacopœia requires that opium shall contain ten per cent. of morphine: so that the Minnesota production came fully up to the stand-

ard. But, for some reason, it was concluded that the production of opium would not be profitable, and it is not likely that this industry will be added to the resources of our State, at least at present.—*Northwestern Lancet.*

THE EDITOR OF "THE LANCET'S" CONFESSION OF FAITH.—Some time before his death, the late Dr. James G. Wakley made a special request that the following confession of faith should be introduced into any notice of his life which might appear in the pages of *The Lancet:* "Feeling my deep responsibility to God for the position in which in His providence He has placed me, I desire to testify to the comfort derived during my sickness from a lively faith in our Lord Jesus Christ, and that I die in the sure hope of a glorious resurrection."

THE MEDICAL QUIZ OF JEFFERSON MEDICAL COLLEGE.—Drs. L. Wolff, R. Leaman, A. P. Brubaker, Orville Horwitz, J. K. Bell, A. C. W. Beecher, and Henry Morris have opened, at the northeast corner of Tenth and Walnut Streets, a convenient and attractive reading-room and club-room for the accommodation of students.

PROVIDING FOR THE FAMILY OF PROFESSOR VON GUDDEN.—A gratuity of ten thousand pounds has been granted from the Bavarian Civil List to the widow of Professor Von Gudden, of Munich, who perished with the late King of Bavaria in the lake at Castle Berg. He left a family of eleven children.

E. O. SHAKESPEARE, M.D., having returned to this city from his special mission to study cholera at its home in India, was honored by a large reception by the profession of Philadelphia and vicinity, on the 29th ult., at the Hotel Bellevue.

THE AMERICAN ACADEMY OF MEDICINE will hold its next annual session at Pittsburg, Pennsylvania, October 12 and 13.

THE AMERICAN RHINOLOGICAL ASSOCIATION will hold its fourth annual meeting in St. Louis, Missouri, October 5, 6, and 7.

NOTES AND QUERIES.

ERGOT IN THE THIRD STAGE OF LABOR.

MR. EDITOR,—In your issue of September 18, Dr. J. W. McFarlane, of Pittsburg, criticises my paper of the 4th instant. Will you kindly indulge me with space in your journal to answer him? He says, "Giving ergot to every case seems not only irrational but harmful." I have been using it for the last three years, and, though it may *seem* irrational, I certainly have not *found* it harmful. In fact, my experience has been exactly the opposite, as stated in my paper.

Labor is becoming no longer a physiological process, or, if it be such, pathological agencies mar the normal results and we must lend our aid. No man would think of withholding his services, when asked for a dysmenorrhœa, on the ground that menstruation "is a physiological process."

When labor is truly a physiological process, any old granny who knows enough to tie and cut the cord will do for an *accoucheur*.

In my paper I distinctly state what I expected to accomplish when I give ergot after the expulsion of the placenta. I say, "It lessens or prevents after-pains, it hastens involution to a marked degree, and it reduces to a minimum the dangers of septic absorption." I do not claim for it that it will "ward off septic trouble and what not," but that "it will *reduce to a minimum* the dangers of septic infection."

In the last paragraph but one of his criticism the gentleman strikes the key-note of the whole position. He says that after his favorite manipulation, "in certain cases where patients are feeble" he "followed it up with ergot to *guard against possible danger*." (Italics are mine.) Now, what more than this do I advocate? It is only to guard against possible danger that I give ergot; and where a man, as one in country practice, is not of easy access to his cases, it is a decided comfort to know that everything possible has been done to guard against possible danger either of hemorrhage or of septic absorption.

Hoping, sir, you will pardon me for encroaching on your space, I remain

Very truly yours,
V. M. REICHARD, M.D.

FAIR PLAY, MARYLAND, September 20.

A RARE OPPORTUNITY is offered to a regular practising physician to secure a paying city practice in Cleveland, Ohio. The office has been established sixteen years, is well located and furnished, and commands a profitable practice, to whom the purchaser will be personally introduced and commended.

Communications for particulars, to receive attention, must be accompanied by reference as to professional and personal standing, and addressed to

J. W. RABE,
835 Market Street, Philadelphia.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 12, 1886, TO SEPTEMBER 25, 1886.

FIRST-LIEUTENANT W. W. R. FISHER, ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect September 10, with permission to apply for one month's extension. F. O. 88, Department of Arizona, September 1, 1886.

FIRST-LIEUTENANT CHARLES M. GANDY, ASSISTANT-SURGEON.—Assigned to duty at Fort Concho, Texas. S. O. 131, Department of Texas, September 18, 1886.

FIRST-LIEUTENANT PHILIP G. WALES, ASSISTANT-SURGEON.—Resignation accepted by the President, to take effect November 5, 1886. S. O. 212, A. G. O., September 11, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED SEPTEMBER 25, 1886.

AUSTIN, H. W., SURGEON.—Granted leave of absence for thirty days, September 16, 1886.

GOLDSBOROUGH, C. B., SURGEON.—Promoted and appointed Surgeon from October 1, 1886, September 9, 1886.

YEMANS, H. W., PASSED ASSISTANT-SURGEON.—Granted leave of absence for ten days, September 16, 1886.

BEVAN, A. D., PASSED ASSISTANT-SURGEON.—Promoted and appointed Passed Assistant-Surgeon from September 1, 1886, September 7, 1886. Granted leave of absence for thirty days, September 7, 1886.

GLENNAN, A. H., PASSED ASSISTANT-SURGEON.—Promoted and appointed Passed Assistant-Surgeon from September 1, 1886, September 7, 1886.

NORMAN, SEATON, ASSISTANT-SURGEON.—To proceed to Vineyard Haven, Massachusetts, for temporary duty, September 9, 1886.

BAILHACHE, P. H., SURGEON.—Granted leave of absence for thirty days, September 25, 1886.

VANSANT, JOHN, SURGEON.—Granted leave of absence for thirty days, September 24, 1886.

BRATTON, W. D., ASSISTANT-SURGEON.——Relieved from duty on Revenue Steamer "Corwin;" ordered to duty at Marine Hospital, San Francisco, California, September 20, 1886.

PHILADELPHIA, OCTOBER 16, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE ASEPTIC AND ANTISEPTIC TREATMENT OF WOUNDS.

Delivered at the Pennsylvania Hospital. Opening Lecture, October 2.

BY THOMAS G. MORTON, M.D.,

One of the Attending Surgeons.

GENTLEMEN,—I have a few cases to present to you this morning which I think will be of interest, but before doing so wish to refer to the method now pursued in the treatment of wounds in this hospital. When I was a resident physician here, more than twenty-five years ago, and during the succeeding years as attending surgeon, the plans of treatment were very different: they were constantly changing, and varied with the convictions or whims of the surgeon on duty, in the hope of securing better results after surgical operations and in the treatment of wounds generally. Does not the very fact that there has been no one well-defined plan followed here or in any other hospital, or by any surgeon, show that no plan was universally acknowledged to be best and that all were more or less unsatisfactory? I can recall cases that were attended with bad results, and many that ended fatally, which under the present mode of wound-treatment would unquestionably have recovered, and lives were lost which should not even have been imperilled.

Within the last few years a great change has occurred. The principles of antiseptic surgery as originated and developed by Lister have now become firmly established, and are revolutionizing wound-treatment. This system, as it may now be called, has been so perfected that it has reached a point which permits me to show you to-day results entirely unattainable by any other means known among mankind.

Antiseptic surgery had never been thoroughly introduced in this hospital until within a comparatively recent period, and this new departure has been effected chiefly through the great interest in the subject and attention devoted to it by two of our resident physicians,—Dr. Charles B. Penrose and my son, Dr. Thomas S. K. Morton. The results of their careful and scientific work have necessitated the general introduction of antiseptic surgery in dressing wounds, whether accidentally inflicted or made by the knife of the surgeon.

To these gentlemen too much credit for perseverance and skill cannot be given. I believe that you will see as a result of their labor results which will convince you that antiseptic surgery, if properly carried out, is *scientific surgery*, and to my mind *there is none other*. The first case to illustrate my remarks is this patient, aged 46 years, who leaves the hospital to-day perfectly recovered. He was admitted on the 8th of September last, with a compound, comminuted, depressed fracture of the skull in the right parieto-frontal region. In this case the trephining operation was done under strict antisepsis. The man was up and about the ward on the fourth day; and when the primary dressing was removed it was found that the catgut sutures placed to keep the wound together, as well as the catgut drain, had entirely disappeared, and complete primary union had occurred.

In the second case, one of old ununited fracture of the radius, with considerable absorption of bone, following a simple fracture, where several attempts had been made to obtain bony union, but without success, I was satisfied that there was no use of repeating the old operation, because there was a gap between the ends of the radius. In order to fill this up, I was obliged to resect the ulna. I therefore first removed an inch and a quarter from the lower third of the shaft of the ulna; this brought the ununited ends of the radius together, which were freshened by sawing off the ends of the bone. The ends of the radius and ulna were then united by chromicised catgut ligature. This operation was performed twelve days ago under strict antiseptic precautions, as in the former case. There has been no rise of temperature since the operation, and the wound has not been disturbed since the first dressing was applied. The patient has been about the wards since the second day, and he is and has been perfectly well in all respects.

Cases of amputation, when dressed in the manner described, are allowed to go for two or three weeks before the primary dressing is taken off, when complete union

is found to have occurred. In fact, the dressings are usually not disturbed until the patient is considered ready to go out. Curiosity tempts the surgeon to examine these cases, but the first dressing should not be removed unless absolutely demanded by a rise of temperature.

Now, these are facts, and they are circumstances which I have not seen attending the amputations or the operations of surgery of former years. To what must be attributed these wonderful results? Why this contrast with the old practice, often requiring weeks and months in bed, with suppurating wounds and daily dressings, and occasionally hemorrhage and exhaustion and surgical fever? The question is answered when I tell you that it is due to antiseptic surgery and aseptic appliances. But, gentlemen, antiseptic surgery means scientific *antiseptic* surgery, and not partial antiseptic surgery. If you adopt antisepsis as a principle, it must be carried out absolutely. Do not omit in your treatment the minutest precaution which might assist in securing the results which you desire to obtain, and which you always will obtain if you are not negligent.

Certain facts must be borne in mind. If you could get absolute cleanliness you could get along without antiseptic appliances; but, as this is not possible, we adopt means which prevent contamination and infection in our wounds. We have often unfortunate surroundings, especially in hospital practice, against the influences of which all our efforts at cleanliness are unavailing. We, therefore, must have agents which will destroy micro-organisms, which are present everywhere, and by their growth breed fermentation and disease.

I show you to-day what I mean by aseptic dressings, which are suitable for every case, and are of universal application. Let me remark, however, that if these statements which I have made to you are true, then the surgeon who does not carry out antiseptic treatment does not give to patients under his care that security against infection, disease, and even death, which modern science has proved to be absolutely sufficient. If the surgeon does not obtain the results which other surgeons who practise antiseptic surgery obtain, then he should be held responsible; such a surgeon will be known by his results. If his operations are followed by prolonged suppuration, erysipelas, or pyæmia, he would, very likely, be condemned for not adopting the means which are at his command. These surgical complications are due to fermentation dependent upon parasitic organisms. The presence in the wound of these micro-organisms can absolutely be prevented by antiseptic dressings.

Certain agents are recognized as germicides,—carbolic acid, salicylic acid, boric acid, resorcin, and iodoform; but the most efficient is the bichloride of mercury. It is odorless, inoffensive, and can be used in such dilute solutions as to be free from danger to the patient while destructive to lower forms of life. We never use solutions stronger than one part of the bichloride to a thousand parts of water. A solution one-half this strength is commonly used externally, and as a douche to wounds while operating, and weaker solutions, down to one part to five or ten thousand parts of water, are employed for dressings. We always wash out the stronger solutions where there is possibility of retention in a cavity with risk of absorption, by much weaker ones. The same precaution may be observed with iodoform when it is brought in contact in bulk with raw surfaces. One of our residents, who was handling the solutions every day, was slightly affected by mercurial poisoning during this year; but with ordinary care such results should not occur to either patient or surgeon, unless through marked susceptibility.

Having shown you some examples of the good effects of these dressings, I will proceed to explain them in detail. In the man with the depressed compound fracture of the skull just presented to you, as I have already described, we cleaned the entire scalp with soap and water, and shaved it around the wound. The bare surface of the scalp was then washed with the stronger solution of bichloride of mercury, and towels wet with this solution were placed around the field of operation. The knives and instruments, which are always boiled after being used, and, if possible, also before, were carefully cleaned and kept immersed in a tray of three-percent. carbolic acid solution. The bichloride solutions dull the knives, so we use carbolic acid to keep them in instead. A douche of (1–2000) bichloride solution was directed from time to time upon the wound by an assistant during the operation of trephining and while the several pieces of com-

minuted bone were removed, and while the fragment of bone was elevated which had been depressed. In order to insure freedom from the accumulation of any serous or bloody discharge, we placed several filaments of catgut ligature, which drains by capillarity but will not convey pus, in the bottom of the wound and led them out the angle. This catgut had been rendered aseptic by preparation in a carbolized solution. In from five to seven days it becomes completely absorbed. If it is desired to avoid such rapid absorption, a catgut thread treated with chromic acid may be used, which is harder than the other and requires double the time for absorption. They are made sufficiently pliable to be used for ligatures to bleeding vessels or for stump-drains. They are cut off short, and never give rise to irritation, and need not give the surgeon a thought after their introduction. The wound is brought together as accurately as possible by interrupted catgut sutures. The wound having been again irrigated, the line of suture was covered by a small strip of protective made of silk treated with varnish and coated with dextrine, and a damp pad of bichloride gauze, thickly sprinkled with iodoform upon its skin surface, then placed on the part, and the whole held in position by a wet bichloride gauze bandage.

After getting the wound thoroughly aseptic, it is not possible for any parasite to live beneath the dressings. The surroundings of the wound were also made clean, and no infection can occur from without.

The gauze which I show you is an admirable material for wound-dressings. It is exceedingly cheap, and has wide interspaces, so that discharges are not pent up around the wound. It is immersed in a solution of one to one-thousand of bichloride of mercury. Over the gauze is usually placed a large pad of dry absorbent cotton which has previously been treated with the 1–1000 solution; the dressings are kept in place by a bandage, which is also made of gauze treated in the same way. After this is in place we do not care how many germs or other micro-organisms are floating in the air, they cannot infect the wound. You see in this patient what I challenge surgery anywhere in the world to produce without aseptic or antiseptic dressings,—a compound comminuted fracture of the skull, with serious depression, requiring trephining, completely cured by primary union in twenty-four hours, without fever or systemic disturbance whatever. This perfect result is due to antiseptic surgery and its proper application. In all my experience in this hospital and elsewhere, previously, I have never seen a case of this kind get well by primary union. The result was obtained solely by avoiding local irritation, while the ferment of suppuration has been kept away by securing an absolutely aseptic atmosphere.

You will hear some surgeons decry antisepsis in surgery. I have been a sceptic myself. You may hear them laugh about your precautions, and declare that they can get just as good results without them. But go and see their cases, look at their hospital wards, find out the length of time their cases remain under treatment, and whether erysipelas, cellulitis, and pyæmia ever occur in their practice. Observe, compare, and reflect. This is the only practical way to test the merits of treatment.

I have seen, but years ago, several cases of pyæmia at one time in the wards of this hospital; and one of the surgeons actually resigned because of the unfortunate results of his operations. In 1867 I was so much impressed with the necessity of greater cleanliness in the treatment of wounds that I devised this hospital ward-carriage to carry the dressings around the wards; it is also provided with a tank for supplying a douche of fresh water for the wounds; the basins which previously were placed under each bed were discarded, and sponges done away with and oakum substituted. When the basins and sponges were thus abolished, pyæmia greatly diminished in frequency. Forced ventilation was afterwards introduced, and by these combined means pyæmia was lessened, but not entirely eradicated, although for a period of more than five years, owing to scrupulous cleanliness and great care in every direction, not a single case of this dreaded disease occurred in this hospital.

Considered from the economical standpoint, it may strike you that this is not a cheap method of dressing wounds. As regards the first cost this may be true, but if you consider the saving in bandages alone —of one dressing in three or more weeks— over daily dressings, you will see that it is far less expensive than the former plan, to

leave out of consideration the time of the surgeon or the feelings of the patient. When the better results are taken into consideration, the greater safety and lessened mortality after operations, I think that you will agree with me that the expense is trifling, and that the antiseptic method is worth all the trouble that it costs to attain such results.

When you see, as you have to-day, that we can even open the skull, and resect a bone, and do this without any inflammatory reaction whatever, you obtain an idea of the possibilities of antiseptic surgery.

In private practice I treat my cases just as I do in the hospital. By means of a douche and a rubber tube you can keep up a stream of bichloride solution upon the field of operation. I carry with me a solution of corrosive sublimate, of the strength sufficient, if half a drachm of it be added to a quart of water, to give me a 1–1000 solution, which I can also use for dressings. The hands and finger-nails of surgeon and assistants are cleansed by scrubbing with soap and water, and then washed in this antiseptic solution. A rubber sheet (previously cleaned) should be placed under the part to be operated upon, in order to carry off the washings and discharges. When the lower extremities are to be operated upon, it is well to elevate the head of the bed by placing bricks under the posts, or by a special apparatus in the operating-table, which I exhibit here; a tray is attached to the foot of this table to catch the waste. In operating you will require something to absorb the discharges and cleanse the parts better than a towel. We use commercial sponges in the hospital, bought by the bale, and put through a bleaching and cleansing process. Thus prepared, they cost about half a cent apiece, and are used but once.

I will now show you two cases which require in each an amputation of the leg, and our method from first to last will be with a view to the strictest antisepsis. The first case is one of crush of the tarsus, in which an unsuccessful attempt has been made by my predecessor to save part of the foot by a Pirogoff amputation. Sloughing of the flaps has occurred, and an amputation of the limb higher up is demanded.

I shall now apply the principles already explained to you in performing this operation and in dressing the stump afterwards. I am partial to the Teale method of amputation of the leg, because it gives the best stump for an artificial limb, the cicatrix being at the side.

[The patient, a man 20 years of age, was then etherized. After the leg was washed with soap, shaved, and cleansed with bichloride solution, an Esmarch bandage (previously disinfected) was placed on the limb. The field of operation was next uncovered and surrounded with towels wet with the same solution. The knives were kept in the tray immersed in a three-per-cent. solution of carbolic acid. The circumference of the limb was taken at the place where it was intended to divide the bones; the long flap was then mapped out, rectangular in shape, one-half the circumference of the limb; the short flap was one-fourth the length of the long flap. The arteries were then tied with carbolized catgut, and the wound carefully cleansed of all spiculæ of bone or blood-clots; a few catgut threads were introduced as a drain, the flaps brought together with interrupted sutures of catgut, the protective placed over the sutures, and iodoform and bichloride gauze was applied. The whole stump was finally covered with dry absorbent cotton (previously treated with a solution of bichloride), kept in place with a wet gauze bandage similarly treated with the mercurial solution. The patient was then covered up warm and a bottle of hot water placed to the remaining foot.]

These dressings will remain undisturbed for three weeks or longer, unless some unexpected symptoms appear calling for earlier interference.

The second case I show you has just been admitted: he is 37 years of age, and has sustained a severe crush of the right leg, has a simple fracture of the right clavicle, and several ribs on the same side have been also fractured, and he has a crush of the left tarsus. His condition is serious, but with antiseptic precautions he ought to do well. The right limb requires amputation, for bones, muscles, nerves, and blood-vessels are concerned in the crush; the left foot will probably be saved; we shall at least make the attempt.

[Amputation of the upper third of the leg was performed, with the same precautions in regard to antiseptic dressings.]

ORIGINAL COMMUNICATIONS.

A CONSIDERATION OF THE BACTERIA OF SURGICAL DISEASES.

Read, by invitation, before the American Surgical Association

BY HAROLD C. ERNST, A.M., M.D. HARV.,

Demonstrator of Bacteriology in the Medical School of Harvard University.

VERY many observations have been made, extending over a long space of time and by many different observers, with the object of determining the etiology of the pus-forming processes in man. Before our knowledge of bacteriological methods was as precise as is now the case, such experiments as those of Councilman (*Virchow's Archiv*) and others were considered to be conclusive. These experiments showed, or seemed to show, that the introduction of simple irritant substances into the animal tissues was sufficient to set up a more or less marked degree of irritation, followed by suppuration and the production of a localized or sometimes of a general purulent process. The materials used were croton oil, turpentine, and the like, and the results observed after their introduction into animals were ascribed to a specific power which they possessed, which could, and generally did, produce pus-formation when such materials came in contact with animal tissues. These experiments seemed conclusive at the time they were published, but, with our more recent and intimate knowledge of the bacteria, their fallacies are easily to be perceived, and are seen to lie very largely in the imperfect methods taken to prevent the activity of bacteria, and the fact that these latter were not sought in the lesions produced by means which would lead to their detection if present. It is not surprising, therefore, to read the results of Klemperer in his admirable paper upon this subject (*Zeitschr. f. klin. Med.*, Bd. x. S. 198, and *Fort. d. Med.*, 1886, S. 34). Thinking, and with apparently good reason, that the results of other observers might be due, in part at least, to the imperfect sterilization of the *skin* of the animals experimented upon, this author made all his inoculations at a point which had been just previously seared with a red-hot iron, and again used the actual cautery at the point of inoculation after the operation was over. Of course, the syringe and material employed were thoroughly sterilized in the usual way. Experiments were made in large numbers, with acids, alkalies, cantharides, mustard oil, petroleum, and other irritating materials, and upon rabbits, guinea-pigs, and mice. Pus-formation *never* occurred: at the most, the only sign of any local or general disturbance being a moderate localized serous effusion. After the use of croton oil or mercurial injections, there occurred in some cases a firm necrotic (diphtheroid) infiltration,—Weigert's acute coagulation-necrosis. In only three of a large number of cases did suppuration occur, and in all of these cases micrococci were found in the pus, and the observations were therefore considered imperfect.

The observer concludes that the strongest chemical cannot produce suppuration without the presence of bacteria, and his results certainly seem to support this view. He found also a micrococcus, which under ordinary circumstances would produce no suppuration upon inoculation into animals, but which would set up a flow of pus if an irritation were produced such as would result after the introduction of acrid materials into the tissues.

Scheuerlin (*Von Langenbeck's Archiv*, Bd. xxxii. Heft 2) has also investigated this question, and has come to the same conclusion as Klemperer, that no suppuration will occur without the presence of micro-organisms. His method of experimentation was to place from one to four drops of the irritating substance in capillary tubes. These tubes were sealed, sterilized in the moist chamber, and introduced under the skin of rabbits with all possible antiseptic precautions. When the incision made for their introduction was thoroughly healed, taking six days as a rule, the tubes were broken under the skin, and the animals were killed in from four to eight days. Thirteen irritating substances were used, such as oil of turpentine, croton oil, oil of mustard, formic acid, etc., with distilled water as a control. In only one case was suppuration observed, and bacteria were found in this one.

The point being determined, therefore, that there is at least a very strong probability that no suppuration occurs without the presence and activity of bacteria, the study of the organisms concerned in these processes becomes at once of great interest.

Pasteur was one of the first to investi-

gate the subject, and his *vibrion septique* was one of the first of the organisms connected with a septic process with anything like certainty (*Bull. de l'Acad. de Méd.*, 1877, p. 793). Since that time "the micrococcus of pus" and like expressions have been commonly employed as denoting a single organism which might be held responsible for all purulent processes, but with unreasonable inaccuracy, as later investigations have shown. In other words, there is not one but a number of pus-producing bacteria, which have been fairly well identified and described, and there is no reason to suppose that this number will not be added to as the investigations in this direction are proceeded with.

Rosenbach was the first observer to differentiate more than one variety of pus-forming micro-organism in man ("Micro-organismen bei den Wundinfektionskrankheiten des Menschen," 1884), and was quickly followed by Krause, Passet, Hoffa (*Fort. d. Med.*, 1886, S. 75), and others, working in the same direction. Of course, the pioneer in this as in most other of the exact work in modern bacteriology was Koch, who gave indications of the direction and methods of research in his classic "Wundinfektionskrankheiten."

Of the bacteria concerned in pus-formation which have been found in the human body, and shown to possess pathogenic properties by inoculation experiments upon animals, there are at least twelve varieties which have been described with sufficient accuracy to make it possible for any observer to identify them. This identification, however, is not a simple matter of staining reaction and microscopic observation, as is the case with the bacillus of tuberculosis, but includes all of the means adopted for the classification of micro-organisms from a bacteriological point of view,—not, however, from a botanical stand-point.

The "points" of any bacterium, which form collectively the diagnostic evidence of its place in the classification, are: 1, its form, size, and arrangement; 2, its power of motion or not; 3, its behavior upon the three great classes of culture-media, nutrient gelatin, nutrient agar-agar, and solidified blood-serum, including the form and color of the colonies, and its appearance upon plate-cultures; 4, the temperature at which it flourishes best; 5, the rapidity of the development of the colonies; 6, whether it produces spores or not; 7, whether or not air is necessary for its growth,—aërobic or anaërobic; 8, whether it produces gas or not; 9, its behavior in gelatin,—that is, whether it does or does not liquefy the nutrient gelatin; 10, its behavior towards staining-materials; 11, its pathogenic properties when inoculated into the lower animals.

All of these points must be investigated when it is desired to obtain complete evidence in regard to any special bacterium, and sometimes it is necessary to go through them all before it can be determined that it is one rather than another variety which may be under observation. From this statement it may be easily seen that it is occasionally a difficult matter to say with what organism a given observer has been working.

Rather than to run over all the work of each one separately, in order to give a clear idea of what has been done by the various observers in this line of investigation, I have thought it best to give a summary of the various bacteria thus far found in the "infectious wound-diseases" of man, according to the above method of classification. In this it seems to me as if a clearer idea of them could be conveyed than by any other hasty method.

1. In the first place comes the Staphylococcus pyogenes aureus, very abundant in pus, first described by Rosenbach ("Mikro-organismen bei den Wundinfektionskrankheiten des Menschen") and Passet ("Aetiologie der eiterigen Phlegmonen des Menschen"). They are cocci of variable size, occurring in masses, and often as diplococci, of an average diameter of 0.87 μ. On agar-agar at 37° C. they grow as a glistening raised colony, two to four millimetres broad, of a bright orange color. This color may often appear only after some time, and is then accompanied by a smell like that of sour paste. In gelatin there is generally a cloudy, grayish streak, which after about three days becomes of a yellowish, finally orange color, and liquefies the gelatin, into which the colony sinks. By a needle plunged into agar-agar there is presented a cloudy, beaded yellowish line, which becomes opaque after twenty-four hours, and later of an orange color. There is a layer three to four millimetres broad, extending over the surface of the agar-agar about the point of

entrance of the needle. On sterilized potato the colony has an orange-yellow centre, with a thin, whitish, almost transparent border, which gradually becomes thicker and yellow. There is also the strong paste-smell. Its growth in blood-serum is exactly as upon agar-agar. It grows best at from 30° to 37° C., somewhat more slowly at summer temperature. It retains its vitality for a long time without oxygen, and produces no gas-formation. It liquefies nutrient gelatin and produces an orange-yellow pigment. Injected into the peritoneal cavity of rabbits and other animals, it will produce death after twenty-four hours, or else a tremendous suppuration which may last ten days or more.

This and the micrococcus of osteomyelitis (Becker, *Deutsch. Med. Woch.*, 1883, No. 46) are probably identical, because the behavior of the two under cultivation is the same; they are the same under the microscope, and the results after inoculation are the same.

2. The Staphylococcus pyogenes citreus found in pus and described by Passet (*l. c.*) has precisely the same properties as the preceding, except that its colonies are colored lemon-yellow instead of orange-yellow. It is not nearly so common as the Staphylococcus aureus.

3. The Staphylococcus pyogenes albus (Rosenbach, *l. c.*) occurs in pus less frequently than the Staphylococcus pyogenes aureus, and has the same morphological characteristics and similar pathogenic properties, but in a milder form, producing as a rule only localized abscesses when introduced under the skin of the lower animals.

4. The Micrococcus pyogenes tenuis (Rosenbach, *l. c.*) occurs in large subacute abscesses mostly, and is a form of micrococcus somewhat larger than the staphylococci, without regular arrangement. It grows on the surface of agar-agar, as a thin, almost transparent layer, and in the substance of the same material its growth is almost imperceptible. It grows very slowly, does not liquefy gelatin, and occasionally some of the larger ones are stained at the two poles by the aniline dyes employed, leaving the centre almost clear.

5. The Staphylococcus cereus albus (Passet, *l. c.*), found in pus, is a micrococcus of irregular size, occurring in masses or occasionally in chains; it grows on plate-cultures with nutrient gelatin as white points one to two millimetres broad. In gelatin the surface of the colony is grayish white, with thick stearin-like drops along the needle-track. On potatoes there is a grayish-white colony of medium thickness, and on blood-serum a grayish-white dull streak. It does not liquefy gelatin.

6. The Staphylococcus cereus flavus (Passet, *l. c.*) is exactly like the preceding, except that it produces a lemon-yellow color somewhat darker than that of the Staphylococcus pyogenes citreus previously described. It is of very rare occurrence.

7. Bacillus saprogenes No. I. (Rosenbach, *l. c.*) is a rather large bacillus containing prominent spores, found by Rosenbach in the white plugs of the follicles of the tonsils. On agar-agar the colony appears as a yellowish-gray, opaque streak, about one millimetre thick, of cheesy, sticky consistency, with irregular edges after some time, and after four or five weeks a foul smell like that of sour cake. It is of very slow growth, produces large spores, and gives out an intensely foul odor when free access of air is allowed; when air is excluded the growth is retarded and the foul smell is delayed in making its appearance. Inoculation into the knee-joint of a rabbit gave a negative result.

8. The Bacillus saprogenes No. II. (Rosenbach, *l. c.*), found in the material from foul-smelling feet, is somewhat smaller than the preceding, and after twenty to twenty-four hours the colony on agar-agar appears as numerous fine points, which enlarge and coalesce, and form first an irregular clear, and then opaque, tough, slimy layer. The smell is that of foul feet. It grows very rapidly, is aërobic and also facultatively anaërobic, and gives its characteristic odor much more quickly by the free access of air than when this condition is wanting. It seems to have mild invasive and pyogenic properties.

9. Bacillus saprogenes No. III. (Rosenbach, *l. c.*), found in the pus of septic gangrene, on agar-agar after eight days at summer temperature, appears as a colony three millimetres broad, of an ash-gray color, not sticky, but of an almost fluid consistency, with a rounded contour. It grows with medium rapidity, reaching its maximum in eight days. There is very rapid fouling of albumen with free access of air; without this the process is slower.

All culture-media except milk produce this foul smell in the presence of this organism. After injection, either subcutaneously or into the joints of a rabbit, there occurred a yellowish-green infiltration with a surrounding redness, as well as the characteristic foul smell.

10. Bacillus pyogenes fœtidus (Passet, *l. c.*) was found in abscesses about the anus, and consists of short staffs with rounded ends, often occurring two or more together, with an average length of 1.45 μ, and a breadth of 0.58 μ. It has slight motion. Plate-cultures in gelatin show after twenty-four hours white points, later becoming grayish-white. Magnified twenty diameters, the colonies appear thick and white in their centres and thick and gray at the edges. In gelatin in tubes, after twenty-four hours there is a soft, grayish-white, slimy layer on the surface, with rather thick, irregular edges. The needle-track is softened at first, and later presents large and small points all along it. Old cultures cloud the gelatin at the upper portions. On potato there is a glistening luxurious growth of a clear brown color; on blood-serum, a thick grayish-white streak. It grows rapidly, and does not liquefy nutrient gelatin. Subcutaneous injections and those into the abdominal cavity produce death in guinea-pigs and mice after twenty-four hours. The bacilli are found in the blood, but not at the point of inoculation nor in the organs.

11. Streptococcus pyogenes (Rosenbach, *l. c.*) was found in the pus of an erysipelas-like process. It is a micrococcus occurring in chains of from two to thirty, and of from 0.58 to 0.73 μ in diameter. On plate-cultures in gelatin it produces fine round granular points. In a streak of the needle the culture is thickest at the middle, of a light brown color; its contour becomes thicker, swells up, and finally assumes a terraced form. Needle-punctures in gelatin show a delicate layer around the entrance of the needle, the needle-track itself presenting fine points of growth, at first very sparse, but later larger and much more numerous. In agar-agar at 35° to 37° C. there is a string-like, grayish-white line with points all along it, and no surface-layer. On cooked potato it does not grow well. On blood-serum it grows along the needle-track as a thin, string-like colony. It grows best at 35° to 37° C., much more slowly at summer temperature. It grows slowly, the colony being but two to three millimetres broad after two or three weeks in surface-culture. After four months the culture is almost dead. It may be renewed in fresh nutrient material. It will decompose albumen in a vacuum, does not liquefy gelatin, and upon inoculation in animals produces a very severe spreading, erysipelas-like suppuration.

12. Streptococcus erysipelatis (Fehleisen, "Die Aetiologie des Erysipelas"), found in the lymph-channels during erysipelas, is a small micrococcus occurring in pairs or in chains, especially upon cultivation in bouillon, of about 0.3 to 0.4 μ in diameter. On plate-cultures with gelatin it occurs in fine round granular colonies. Needle-cultures in gelatin after twenty-four hours show very fine white points or flecks the length of the needle-track, which later become a homogeneous white streak. There is either no, or very slight, growth upon the surface of the gelatin around the point of entrance of the needle. In agar-agar it grows very sparsely over the whole surface, in small, almost imperceptible colonies. On blood-serum at 37° C. the colony is almost exactly of the color and nearly indistinguishable from the serum itself. It develops best at from 20° to 30° C., grows slowly, and produces in rabbits a sharply-defined, spreading redness, without suppuration. It always occurs in the lymph-channels of the skin in erysipelas. It has been tried in a number of cases on man, and in these produced a typical erysipelas.

13. Bacillus pyocyaneus (Gerrard, "De la Pyocyanie et de son Microbe," 1882), found in green pus, is a short, fine rod, very likely to be mistaken for a micrococcus. In plate-cultures with nutrient gelatin, after two or three days the whole of the plate has a clear green tint, the colonies liquefying the gelatin in a funnel-shaped depression. Under a low power, the colonies appear round, somewhat yellowish, and glistening with clear granular edges.

Needle-cultures in gelatin after twenty-four hours liquefy the upper layer of the gelatin in a funnel-shaped depression, with a fluorescent coloring of the upper portion. The liquefaction later extends out to the side of the test-tube, and the whole of the gelatin takes on this clear fluorescent appearance. In agar-agar there is a moist greenish-white colony, whilst the

whole of the agar-agar is colored with a diffuse fluorescence. On potato dry colonies of a rust-brown color appear, which turn green with ammonia and red with acids. It grows rapidly; will not grow under mica (glimmerplatte), and liquefies nutrient gelatin. Guinea-pigs die after cultures of this organism have been injected into the abdominal cavity (Koch). Rabbits survive its injection into the blood-current.

14. Pneumoniacoccus-like bacillus (Pneumokokken ähnlicher Bacillus, Passet), an organism found in pus, occurring as micrococci,—very rarely as short staffs,—in contradistinction to the pneumoniacoccus of Friedländer, which very often has this form. On plate-cultures small grayish-white nodules appear, made up of the cocci. Needle-cultures in gelatin show after twenty-four hours a grayish-white hemispherical nodule on the surface, with no growth in the body of the nutrient soil. After three or four weeks there appears a brownish color in the gelatin, and a foul odor. On potato, at 37° C., there is a thick, soft, whitish, glistening layer, with no gas-production. Its growth is rapid, it produces no gas, and does not liquefy gelatin. Injected into serous cavities it produces a suppurative process, but has almost no effect after subcutaneous inoculation. It has no result at all in inhalation-experiments.

This summary includes all the organisms which have yet been described with a sufficient degree of accuracy to permit of their classification, and which have been found in the purulent or inflammatory processes in man. It is made up from the work of the various observers spoken of in the earlier part of the paper, and is based upon the excellent tables of Dr. Eisenberg. It does not, of course, include those organisms described by Koch in his "Wundinfektionskrankheiten," because they were connected solely with the lower animals by that observer. The summary gives us, however, a very comprehensive view of the work that has already been done, and of the number of organisms which have already been found in the various suppurative and inflammatory processes occurring in man. Unquestionably the subject is not yet exhausted, and additions to the list may very probably be made.

I have been interested in examining such cases as I could gain access to of graver forms of the suppurative process than simple acute abscesses and the like. These latter have been investigated in such numbers by the observers already alluded to—Rosenbach, Krause, Passet—that it hardly seemed worth while to go over exactly the same ground again in the same way. I have selected therefore, so far as was possible, severe cases of long standing and those where there had been no access to the air previous to the time of examination. Cases of this sort, fulfilling all the indications required, are not especially easy to find, and my thanks are due to Drs. J. C. Warren and E. H. Bradford for the material which they have placed at my disposal.

In chronological order the cases which I have examined are as follows:

I. Cultivations were made from an abscess of slow growth occurring at the seat of an ununited fracture of the left humerus of over a year's standing. No external injury to the parts was apparent, and there was no opening until the incision was made through which the pus was obtained for cultivation. Cultures were made from the pus which flowed out and from the wall of the abscess. Colonies of the Staphylococcus aureus and albus made their appearance upon the nutrient material in the course of a few days, were separated from each other, and carried through a number of generations. This case is interesting because the diagnosis of tuberculosis was made from the clinical symptoms, but a very careful examination of cover-glass preparations of the pus and of scrapings from the wall failed to show any indication of tuberculosis either in the way of giant-cells or of the bacilli of tuberculosis.

II. A large perinephritic abscess of several weeks' duration. Cultivations made from the pus and from the abscess-wall showed the presence of the Staphylococcus aureus and albus, which were separated and grown for some time. The case terminated fatally from pyæmia, and micrococci corresponding to those in the cultivations were found in microscopic preparations of the valves of the heart, in the kidney, spleen, and blood.

III. A skin-disease of the knee in a girl of 20, of some years' standing. An incision was made through the growth, a

flap turned back, and cultivations made from beneath this by scraping the needle over the surface. The colonies which made their appearance were the Staphylococcus citreus and albus, which also were separated and carried through a number of generations. Sections were made of a portion of the diseased skin of the knee which had been put into absolute alcohol at once after removal. Micrococci corresponding in size to those in the cultures were found in large numbers just below the layer of flat epithelium, with colonies running down at frequent intervals between the cells into the deeper layers of the skin. The microscopic appearances in gross showed the presence of giant-cells and granulation-tissue, with some proliferation of the epithelial cells into the deeper parts with a few clusters of epithelial cells. The most careful search through a number of sections, by Dr. W. F. Whitney and myself, failed to show the bacilli of tuberculosis.

IV. Perinephritic abscess of several weeks' duration, with a small opening which was only a few hours old. The abscess was opened by an incision through the skin made upon the opposite side of the body from this sinus, and cultivations were made upon agar-agar from the pus thus obtained. Pure cultures of the Staphylococcus aureus made their appearance in the course of a few days.

V. Erysipelas of the foot four days old surrounding a penetrating wound. An incision through the skin at a point just beyond the line of redness was made, and cultivations were sown with a platinum-needle from over the bottom of the wound. A pure culture of the Erysipelas coccus was obtained.

VI. Cultivations were obtained from the material in the vagina of a case of vaginal diphtheria after parturition at the Boston Lying-in Hospital, through the kindness of Dr. W. L. Richardson. There appeared, in the course of a few days, colonies of the Staphylococcus albus, and of the Bacillus pyogenes fœtidus,—the latter of which I had hoped to be the first to describe, but which will be seen, by the preceding mention of it, to be credited to Passet.

VII. A case of vaginal diphtheria occurring under the same circumstances as the preceding. Cultivations made in the same manner were productive of colonies of the Staphylococcus albus only. The case was almost convalescent at the time the examination was made.

VIII. A third case of vaginal diphtheria under like conditions as the two preceding, with the exception that there was a considerable amount of pus present in the vagina. This patient was also convalescent. The culture-tubes showed the presence of the Staphylococcus aureus and albus, and of the Bacillus pyogenes fœtidus. There was also present a bacillus resembling the Bacillus subtilis, which was probably due to some contamination occurring during the manipulations.

IX. A case of psoas abscess in a child; a large amount of pus. Opened under carbolic spray and cultivations made from the pus and from the abscess-wall. The result showed a very free growth of the Staphylococcus albus only.

X. A case of hip-disease in a child, with a profuse suppuration about the hip-joint. Cultivations made from the pus as it flowed from the incision and from the joint itself showed the presence of the Staphylococcus aureus and albus. The latter—Staphylococcus albus—was much the most prominent, Staphylococcus aureus appearing in only one tube out of ten in which cultivations were made.

XI. A case of hip-disease in a child, with sinus which had been open for some time. In this case cultivations were made from a fresh opening made to secure drainage, and a free development of the Staphylococcus aureus and albus, and of a fine oval bacillus with no pathogenic properties, was obtained; the latter was probably the so-called Bacterium termo. The Streptococcus pyogenes was also found in this case, making four in all which were obtained.

XII. A case of glanders in the human subject. The body was covered with a large number of pustules, three or four of which were opened and cultivations upon agar-agar and in gelatin were made, the point at issue being to discover whether any of the ordinary forms of bacteria present in pus would be found in this case. As a result, colonies of the Staphylococcus aureus and albus were obtained, as well as two or three colonies of a fine bacillus answering the description of the organism found in this affection by Gaffky.

XIII. A case of lumbar abscess, with possible caries. Cultivations made from

the pus flowing out after incision of the abscess resulted in the development in a few days of a number of elevated, glistening, yellowish colonies, which, upon microscopic examination, were found to be made up of pure cultures of very fine, short, straight bacilli.

XIV. Psoas abscess in a child. Cultivations from the pus obtained in this case showed the presence of the Staphylococcus cereus flavus of Passet, so called, and of the Staphylococcus aureus.

XV. Psoas abscess in a child. Cultivations from the pus of this case gave, as a result, colonies of the Staphylococcus albus, and of a bacterium of which a more detailed description will be given farther on.

XVI. A case of abscess of the arm in a man. There was extensive purulent infiltration over the region of the shoulder and upper arm, extending into the left side, and penetrating into and between the various muscles of the affected parts. A number of cultivations were made with the pus as it flowed out from the freshly-opened wounds, and in the course of a few days very beautiful colonies of the Streptococcus pyogenes were obtained.

XVII. Abscess of the back following caries of the spine, which had existed for some time. The abscess was apparently the size of the fist, of rapid growth, and was situated in the right lumbar region very near the spine. Cultures were made from this case as before, from the pus flowing from a freshly-made incision. After a time, slowly-developing colonies of the Micrococcus pyogenes tenuis were seen to make their appearance, together with colonies of the Staphylococcus pyogenes albus.

XVIII. A case of bubon d'emblée. The swelling was of slow growth, and absolutely no history of venereal infection could be obtained. There were signs of pulmonary solidification, however, and the question as to whether the swelling in the groin might be of tuberculous origin or not became of interest. Upon incision into the tumor, a thick, dark pus was forced out, and cultivations were made, which, in the course of a week, produced colonies of the Staphylococcus pyogenes albus and of the Micrococcus pyogenes tenuis. Two of the glands which were enlarged to the size of marbles were placed in absolute alcohol, and upon several subsequent occasions sections were stained and examined with the greatest care for the presence of bacillus of tuberculosis; the results of such examinations were in all cases negative.

This completes the list of the cases which I have examined. It is not an extensive one, and was purposely, so far as possible, limited to the more chronic processes, and to those where there was and had been no access to the air until the moment of time during which the cultivations were completed. It is, however, important to observe that in every case examined one or more forms of bacterial life were developed upon the nutrient material, and therefore that, so far as these observations go, they tend to refute the assertion that bacteria are not present in the more chronic forms of purulent disease. It is true that they may not be discovered by simple microscopic examination of the fresh pus, but this does not prove that they are not present. Their numbers may be so small that a few cover-glass preparations made up from only a portion of a drop of the pus might easily fail to reveal their presence. Cultivations, however, offer a means for their development, and the presence of but one or two bacteria may be demonstrated in this way in cases where they might be overlooked if any other method of investigation were employed.

In all the cases that I have reported the mode of procedure was as follows,—except, of course, in the diphtheritic vaginæ, where there was necessarily more or less free access to the air. After anæsthesia was complete, the skin over the point selected for the incision was thoroughly washed in a solution of corrosive sublimate, one to one thousand; the surgeon's hands were sterilized in the same solution. The incision was made with a knife freshly removed from the same solution, and as soon as the pus-containing cavity was opened, a platinum needle taken from the flame of an alcohol-lamp was plunged into it, and test-tubes containing nutrient gelatin and nutrient agar-agar were inoculated with the material obtained. The tubes were then removed to the laboratory, and in some cases plate-cultures were made at once, and in others not until twenty-four hours afterwards. A number of the tubes were also placed in the incubator at 37° C., and the conditions of development were observed under these circumstances. Every

one of the bacteria obtained was identified by means of its microscopic appearances, and its behavior under cultivation in various nutrient media on plate-cultures with nutrient gelatin, on agar-agar, etc., so that no name is given to any of the organisms found in the cases reported without a sufficient basis of careful observation. A large number of the bacteria were propagated through from fifteen to twenty generations, and were found to preserve their properties under cultivation during the whole of the time they were under observation, extending from six months to over a year. Owing to my absence abroad during last fall and an unfortunate mistake in regard to the time of my return, a number of the cultures were lost through drying. By this I do not mean that all of any one variety were lost, but that about one-half of the collection I had made from different cases were destroyed. This was to be regretted, because I had kept every bacterium from every case separate, and had carried each one through a long number of cultivations, extending over a great length of time, with a view to the determination of differences, if any existed, in the pathogenic powers of micro-organisms from different cases, but of the same apparent nature, as shown by their appearances under varying conditions of cultivation. This point the accident which I speak of prevented me from investigating, although the results obtained by other authors seem to indicate that there is no such difference as had seemed to me possible when I began this research; and the fact seems to be established that the differences in the pathological changes produced by what we must call the same bacteria are the result of influences other than those peculiar to the bacteria themselves, such as changes of nutrition and method of infection. It is to such differences as these that the varying clinical results produced by the Staphylococcus pyogenes aureus, as seen in osteomyelitis and acute abscesses, must be ascribed; for it seems to be fairly well established that the organisms producing the first and part of the latter processes are identical. The methods of Koch—including of course the employment of solid culture-media—have been used in all cases, as being conducive to greater precision and more definite results than any others that are known. This is especially the case in such an investigation as the present one, for without these methods the differentiation of the various bacteria in the pus-producing processes would be practically impossible.

(To be continued.)

REPORT ON THE PROGRESS OF MEDICINE AND GENERAL PATHOLOGY.

BY J. C. WILSON, M.D.,

Physician to the Philadelphia Hospital and to the Hospital of the Jefferson College.

HAMMER-MAN'S CRAMP.

G. V. POORE, in a recent clinical lecture at the University College Hospital (*Lancet*, August 21, 1886), calls attention to an unusual form of handicraft disease.

The patient, a previously-healthy nail-maker, 25 years old, somewhat addicted to alcohol, and working for long hours at "piece-work" in forging nails with a moderately light hammer, suddenly lost the power to direct the blow accurately, and in the course of a few months suffered so much from inability to wield his hammer and jerking of his right arm when attempting to do so that he was obliged to abandon all attempts at work. Six months later, after treatment, the circulatory, respiratory, digestive, and genito-urinary systems presented no abnormalities of any kind; the temperature was normal, but the pulse rather infrequent,—62 on one occasion, 52 on another. As regards the nervous system, examination of the patient shows his intelligence to be good; the special senses are normal; no headache; the third, fourth, fifth, and sixth cranial nerves apparently normal; the right naso-labial fossa rather less marked than the left; the mouth droops a little on the right side when at rest, and moves a little less vigorously than on the left side; the right upper limb is seldom or never quite still; when sitting up, with the arms hanging by the side, the right arm is the seat of constant slight movements,—elevation and adduction of the humerus and flexion of the elbow. Upon attempts at voluntary movement the spasmodic action of the muscles of the arm is increased, and extends to the deltoid, trapezius, and pectoral muscles. Attempts to use the hammer greatly intensify the spasms and render analysis of the muscle-faults impossible; ordinarily the arm is held

fixed to the side, the wrist is extended, the hand supinated and closed. There is nothing wrong with the lower limbs, except that plantar reflex is more marked on the right side than on the left. Sensation is everywhere normal; the patient is free from pain; attempts at movement are followed by a sense of fatigue and some aching; none of the nerve-trunks are in the least tender. It is evident that the spasm is not now special to the performance of the patient's professional act of hammering: it interferes with the accuracy of all voluntary movements of the right hand, and is noticeable to some extent when he is making no voluntary movement.

This case is of interest not only because of its rarity, but also on account of its difference from—rather than its resemblance to—other forms of handicraft disorders of the nervous system, and especially writer's cramp.*

The sudden onset, with the evidence of slight failure of the right side of the face and right half of the tongue and the exaggerated plantar reflex of the right foot, makes it highly probable that the lesion, whatever it may be, would be found in the motor area of the cerebral cortex on the left side, and that the motor affection is part of a slight hemiplegia. In this connection it is of interest to note that Frank Smith, of Sheffield, has placed upon record eight cases, analogous to the present one, under the name of "hephæstic hemiplegia, or hammer palsy" (*Ἡφαιστος*, Vulcan). Of these eight cases, six were distinctly hemiplegic in character, while two were cases of brachial monoplegia.

The author expresses the belief that the physical basis of the trouble in the case under discussion will be found in thrombosis of the ascending frontal branch of the Sylvian artery. Treatment for several months had been without result, and the prognosis was not good.

These cases extend the limits of the so-called professional nervous diseases, and point to actual cerebral lesions which may arise from over-use of nervous centres. It is probable that constantly-repeated movements that are not really automatic, but require a constant effort of the attention, are more liable than others to produce central derangements.

* [This relation has been recently considered in a paper by the editor of this journal, published in the *Annals of Hygiene* for October.—Ed.]

CLINICAL OBSERVATIONS ON THE ACTION OF ANTIPYRIN AND THALLIN IN ACUTE RHEUMATISM AND PHTHISIS.

R. Johnson (*Lancet*, August 28, 1886) contributes the result of a limited number of observations upon the action of these drugs. The clinical observations were made at the suggestion of Ringer, who had pointed out the fact that the temperature in acute articular rheumatism is often highest immediately after the admission of the case to the hospital, and usually undergoes a considerable fall, sometimes as much as a degree or even two degrees F., in consequence of the complete rest in bed. To escape the possible error due to this action of rest, no medicine, or at most a placebo only, was administered for the first twelve or twenty-four hours. Antipyrin in twenty-grain doses or thallin in one- or two-grain doses was then given at short intervals. In those cases in which the influence of these drugs did not appear to be beneficial, they were superseded by sodium salicylate. Johnson's experience corresponds with that of Dujardin-Beaumetz, that antipyrin in acute rheumatism reduces the fever but does not materially affect the joint-symptoms. This conclusion is at variance with that of many observers, including Neumann and Pribram, who have considered this drug equal to the salicylate in rheumatic fever. With regard to thallin, the general opinion of those who have employed it appears to be that it compares very unfavorably with sodium salicylate in the treatment of acute rheumatism. This view is confirmed by Johnson. He also regards thallin, notwithstanding slight advantages such as rapidity of action, as very inferior to antipyrin in its effect upon the temperature in this disease. He concludes that sodium salicylate "remains *par excellence* the cure for acute rheumatism, but that antipyrin may be useful in those rare cases in which the salicylate fails to exert its apparently specific action on the disease."

In phthisis the effects of antipyrin, in doses of fifteen grains given every four hours, or thrice daily, according to the requirements of the case, are very variable. In some it simply lowers the temperature without improving the general condition of the patient or retarding the course of the disease, whilst in others it is of great benefit,—lowering the temperature, lessening the night-sweats, and improving the

nutrition. On the other hand, the use of thallin in phthisis was followed by no appreciable benefit. Its almost constant effect on the temperature was to greatly increase the daily variations, the minimum temperature being often lowered by as much as 2° F., whilst the maximum remained the same. Each fall of temperature produced by thallin was accompanied by sweating, and the following rise was frequently attended by shivering and in many cases by distinct rigors.

The most important difference in these two drugs, as shown by almost all the cases in which they were used, is in the duration of their effects. The lowering of temperature brought about by antipyrin lasts usually (in these diseases) for many hours; the rise is gradual, and occupies several hours. Thallin, on the contrary, produces a very transitory effect, the rise often beginning within two hours after stopping the drug, being as a rule rapid and attended by shivering. The influence of antipyrin and thallin upon the pulse and respiration was slight.

Johnson calls attention to the following among the toxic effects of these drugs. Nausea and vomiting are not rarely produced by antipyrin in full doses, seldom by thallin. In a case of phthisis, prostration of a marked character followed the administration of antipyrin in three doses of ten, twenty, and twenty grains respectively, and again in a boy to whom three fifteen-grain doses were given at intervals of an hour. In no case did thallin occasion any prostration. Antipyrin is more apt to be followed by profuse sweating than thallin; thallin produces shivering and rigors with considerable frequency, while these effects have rarely followed the administration of antipyrin. The exanthematous eruption first described by Ernest, of Zurich, as occasioned by antipyrin is by no means rare; it consists of small rosy-red spots over the chest and abdomen, and to a less extent on the limbs. The rash may be confined to the face and neck, and then closely resembles that of scarlet fever; it is transient, usually fading gradually in the course of one or more hours. Thallin in rare instances causes a similar rash. During the administration of thallin the urine assumes a dark-green color and emits a strong odor of the drug; this effect rapidly disappears after the drug is stopped. This condition of the urine is of constant occurrence, and closely resembles that so often seen in the surgical wards from the absorption of carbolic acid.

TRANSFUSION AND INFUSION.

Dr. A. Landerer (*Virchow's Archiv*, August 3, 1886) discusses at length the present state of knowledge in the matter of the treatment of blood-losses jeopardizing life, profound anæmia from other causes, and certain forms of poisoning. His conclusions are based upon the now well-recognized dangers attending the transfusion either of blood or of serum, the inadequacy of salt-solutions, and the efficiency of a mixed solution of salt and sugar. His experimental investigations in regard to the latter solution were conducted in the Physiological Laboratory in Leipsic, under the supervision of Professor Ludwig and Dr. Gaule.

The dangers attending the transfusion of blood are illustrated by two cases observed by the author in the surgical clinic. The first of these was that of an eight-year-old boy reduced to the last degree of anæmia in consequence of paralysis of the muscles of deglutition following diphtheria. The details of the operation were carried out with the utmost care in accordance with the accepted rules of procedure. After thirty cubic centimetres of thoroughly defibrinated and filtered blood had been thrown into the left median vein, gasping respiration and facial spasm were followed by sudden death. At the post-mortem examination, the pulmonary artery was filled with fresh clots.

The second case was that of a young woman suffering with acute anæmia. Here peritoneal transfusion (Ponfick) was performed with full antiseptic precautions, three hundred cubic centimetres of blood being introduced. The patient died of foudroyant peritonitis in forty-eight hours.

The investigations of Alexander Schmidt, Cramer, Edelberg, and others have shown that these accidents are due to the development in the drawn blood of fibrin-ferment, which despite the most careful defibrination is occasionally the cause of fatal change in the blood of the organism into which it is introduced. That this change only occasionally occurs does not militate against the objections to transfusion, because in any given instance it can neither be foreseen nor prevented.

Since Goltz has shown that the imme-

diate cause of death in blood-loss is not, as formerly thought, dependent upon loss of hæmoglobin and its result, the deprivation of oxygen, but rather that it is dependent upon certain mechanical conditions, especially a derangement of the relations between the capacity of the blood-vessels and their contents and incomplete filling of the heart with blood, the introduction of some indifferent fluid not injurious to the blood itself, in order to fill the vascular system, became the controlling indication.

For this purpose the 0.6 per cent. alkaline solution of common salt (Kronecker and Sander*) has been regarded as possessing the necessary qualities. In fact, as von Ott demonstrated, animals thus treated after severe bleedings make a better convalescence and repair the loss of red corpuscles and other blood-constituents more rapidly than those in which transfusion with whole or defibrinated blood has been performed.

Furthermore, the transfusion of blood was, even under the most favorable circumstances, followed in almost all cases by fever of longer or shorter duration, usually ushered in by rigors, great mental and physical depression, præcordial distress, frequently by intestinal disturbance, and occasionally by exanthems,—symptoms of the "fibrin-ferment intoxication" of Edelberg.

Efforts to prevent the excessive formation of fibrin-ferments by changes in the methods of defibrinating the blood, as by agitating it with broken charcoal, glass beads, etc., have been without result, nor have attempts to prevent clotting by the admixture of the blood with other fluids led to any practical result.

The author regards with disfavor attempts to prevent coagulation by any admixture of peptone.

A very simple method, yet one not wholly free from objection, consists in a combination of blood-transfusion with the infusion of the solution of salt. This expedient meets one of the objections to the transfusion of blood: namely, that the volume of fluid introduced is frequently too small to correct the mechanical disturbance between the capacity of the vessels and their contents. The admixture of two to three hundred cubic centimetres of blood with seven to eight hundred cubic centimetres of 0.6 per cent. salt-solution affords sufficient fluid on the one hand and reduces the danger of poisoning by fibrin-ferments. This method of "mixed transfusion" will probably be preferred as less dangerous by those who cannot abandon the view that transfusion is the rational procedure.

The use of various forms of serum is not without risk, seeing that they all, with the single exception of horse-serum, contain more or less ferment. Serum is not practical for the further reason that its preparation is too difficult and tedious.

Other fluids containing nutritive substances, as for example milk, have been found to be attended by direct dangers.

Much can also be said against the infusion of salt-solution. In cases of poisoning in which transfusion is required, salt-solutions would be clearly inadequate. In fact, the use to replace lost blood of a fluid which is scarcely more than water, without value in nutrition or force, must be looked upon as at best an unsatisfactory and imperfect procedure. This objection—that such a solution acts merely mechanically—is a serious one. In the words of Landerer, "It is as if one were to offer a hungry man a stone instead of bread." Furthermore, it has not been followed in a large number of cases, especially where there has been large blood-loss, with the hoped-for result. Nevertheless, we have in salt-solution probably hit upon a basis by means of which, with proper additions and modifications, a transfusion-fluid meeting the various indications for transfusion under all circumstances may be made up.

The requirements of such a fluid are as follows:

1. It must be absolutely without danger in itself.

2. It must be readily obtainable under all circumstances, so that in case of necessity it may be procured at once.

3. It must contain the greatest available amount of assimilable substances capable of sustaining animal heat and the powers of the organism.

4. It should be of the simplest possible chemical constitution.

The author believes that in a combination of the alkaline salt-solution (0.6 per cent.) with a solution of sugar (one to three per cent.) we have a fluid which fulfils all these requirements.

* Berlin. Klin. Wochenschr., 1879, No. 52.

The conclusions of the author are as follows:

1. Blood-transfusion is dangerous and useless.

2. The infusion of a solution of common salt does not in really severe blood-loss (more than four and a half per cent.) by any means insure a favorable result.

3. A combined solution of salt and sugar is preferable, because (*a*) it favors and accelerates the natural tendency of the organism to readjustment by favoring the transudation of fluid from the tissues to the interior of the blood-vessels; (*b*) it affords the organism a light and quickly-assimilable nutrient material; (*c*) it more closely resembles the blood in density than the solution of common salt; (*d*) it raises the blood-pressure.

4. The combined solution of salt and sugar may be of use in poisoning by nitrobenzol, chloral hydrate, chloroform, carbon dioxide, etc.

5. In cases of loss of the watery portions of the blood alone, as in cholera, the salt-solution may be more available than the combined salt and sugar solution.

THE HEREDITARY TRANSMISSION OF PARASITIC ORGANISMS.

Professor Max Wolff (*Virchow's Archiv*, July 3, 1886) communicates the result of a series of researches in this connection which he has been conducting since 1884 in the Pathological Institute at Berlin. His conclusions are at variance with those of Koubassoff, who reported that, after injecting pus containing tubercle-bacilli, milzbrand bacilli, the bacilli of malignant œdema, etc., beneath the skin of gravid guinea-pigs and rabbits, he discovered these microbes in the internal organs of the fœtus, and frequently in great numbers. According to this statement, the transmission of the microbes to the fœtus and its infection from the mother would be of very common occurrence.

To this view Wolff by no means accedes. On the contrary, his researches lead him to regard the conditions as by no means favorable to this mode of infection.

1. The first series of experiments were made with milzbrand (anthrax) bacilli. Six animals were inoculated, and died of exquisitely developed milzbrand, with abundant bacilli in all the organs. With the seventeen fœtuses examined the case was wholly different. Microscopical examination of sections from the thoracic and abdominal organs, both with double staining by the method of Gram and without it, and one hundred cultures of material from the liver, spleen, kidneys, and lungs, gave absolutely negative results.

As a further means of control, thirteen young animals were subcutaneously inoculated with fragments of the organs of these fœtuses. Of these two only died of milzbrand; the rest were kept many weeks under observation and remained free from the disease. The author thinks that it is almost certain that the two animals that contracted it were accidentally infected in the laboratory. Both the inoculation and culture experiments were carried out with the most rigorous care. The placental and other intra-uterine structures, as well as the fœtus, remained in all cases free from the lesions of milzbrand.

Wolff concludes that the question of the transmission of the bacilli of milzbrand from the mother to the fœtus is by no means settled in "a positive and constant sense," as Koubassoff, in the communication laid before the Paris Academy by Pasteur, assumed.

2. A second series of investigations were conducted with vaccine. Women were successfully vaccinated towards the end of pregnancy. Two or three days after birth the children of these women were vaccinated, with a perfect result in every case. Uniformly positive results—the details of which are to be published hereafter—proved that the vaccine-contagion had not reached the fœtal circulation; that infection of the fœtus through the mother does not take place in vaccinia any more than it does in milzbrand. It is certainly true that the transmission of variola from the mother to the fœtus does occasionally take place; but well-authenticated instances of the children of mothers suffering from smallpox coming into the world with the eruption are extremely rare.

3. The third series of experiments were conducted with a view of solving the question of the parasitic transmission of tuberculosis. This investigation was carried out in two directions. First, a number of animals already gravid were inoculated with material containing tubercle-bacilli. Secondly, another group was inoculated prior to conception, in order to test the possibility of a bacillary infection of the ovum. The author's researches are not yet con-

cluded; but so far as they go the results are not favorable to the view of the direct parasitic heredity of tuberculosis. To the naked eye no one of forty-two fœtuses exhibited signs of tuberculosis, even where the mother died of exquisite diffuse tuberculosis.

In the human being, tuberculosis of the fœtus and new-born child must be of the most extreme infrequency. Wolff does not deny the occurrence of (parasitic) hereditary tuberculosis, but regards it as extremely infrequent, and looks upon many of the cases of tuberculosis in the new-born as due to direct post-partum infection rather than to intra-uterine transmission. This appears more probable when we reflect upon the great number of risks of infection from their tuberculous parents to which new-born children are exposed. Among them are all manner of modes by which the bacilli-containing sputa may be brought into contact with lesions of the mucous membranes and cutaneous surfaces of the infant.

THE MEDICAL PROFESSION AND PROPRIETARY QUACKERY.

BY SAMUEL S. WALLIAN, A.M., M.D.,
New York.

INCOMPLETE statistics show that the money expended by the people of the United States for secret and proprietary medical preparations aggregates annually more than eighty millions of dollars. When the reasonable statement is added that certainly more than one-half of these exploited remedies are positively detrimental rather than beneficial to their consumers, the subject becomes fairly tragic. Compared with this insidiously-growing evil, war and intemperance are made to seem less formidable calamities.

Limned in detail, the picture would be ludicrous if it were not in its results so fatal as to be actually appalling. For this unsatisfactory state of things there is no specific or easily-suggestible remedy. It may be assumed that ignorance is at the bottom of it, but it is inborn and transmitted ignorance. Generations back of us have contributed towards endowing us with a mania for dosing. The new-born babe takes to its castor oil and saffron as though it had been accustomed to a diet of oleaginous laxatives and other nauseants in some pre-natal state.

It is easy to say, "Educate the community;" but to eradicate a habit at once so pernicious, so wellnigh universal, and so chronic, would involve a disturbance of the very foundations of society. A discouraging feature is that in this connection the acknowledged exponents of the profession are not wholly without blame. See the long list of eminent names appended to unscrupulous panegyrics on one or another form of patent nostrum. See the page on page of popular journals illuminated with flaring cuts and endorsed by the titled names, in display-type, of prominent professors and college presidents, far and near,—all to the end of advertising numberless (sometimes, it may, be meritorious) proprietary preparations. Instance the baby foods. How glibly their proprietors proceed to prove, by authentic chemical analyses, the undoubted superiority of each of these preparations,—and some of them are really triumphs of science,—while their universal and sweeping sale everywhere, proves the sad fact that so many mothers nowadays suppress the maternal instinct, and forego nearly all the mother's dearest recompense, by making half-orphans of their cheated and helpless progeny!

Where shall reform begin? If any degree of success be hoped for, the teachers themselves must first be taught,—physicians must become better informed. In this direction every reputable member of the profession has his personal work, and should not shirk the responsibility. For instance, a prominent medical writer makes the inexcusable blunder of asserting that "the peroxide of hydrogen is simply water impregnated with an excess of oxygen;" whereas every student of chemistry in his first year has learned that the peroxide of hydrogen—more properly *hydrogen dioxide*—is not water at all, contains no free oxygen, but is a definite and distinct compound of oxygen and hydrogen, represented by the formula H_2O_2. Another, referring to the use of the same article as a topical application, says, "It may be used of *full strength;*" whereas peroxide of hydrogen of "full strength," or pure, would act upon tissues to which it might under such teaching be inadvertently applied, much as would the actual cautery.

If prominent professors and specialists trip thus in dealing with its outlines, how shall we wonder at the degree of ignorance exhibited by the average practitioner in relation to simple chemical manipulations? Many an otherwise well-schooled and well-read professional man is entirely at sea when it comes to technical symbols, and stands stupidly aghast before the simplest chemical equation.

Thus, for instance, he has an idea that to make oxygen gas is a difficult and dangerous feat; that some chemical is used which presumably liquefies at high heat; and that explosions are a matter of course, as well as frequent. His conception of the gas itself is that it is a stimulant to the functions, especially that of destructive metamorphosis; and that in some forms of asphyxia, as by carbon dioxide or by drowning, it would often be a desideratum. He scarcely distinguishes between the names oxygen and "compound oxygen," and perhaps vaguely imagines that the latter is a little more complex and expensive, and hence ought to be more efficient than the former. Beyond this rudimentary and indefinite knowledge he has had neither occasion nor inclination to inquire.

At the same time he is acutely sensible that numbers of his clients, induced by extravagant and ingenious advertising claims,—the manufacture of which is now a studied profession,—are wasting much money in openly or secretly procuring some of the many proprietary make-shifts variously paraded under the names of "Oxygen Treatment," "Compound Oxygen," etc. And, however well satisfied he may be that the preposterous claims made for these alluring but usually inert nostrums are unconscionable exaggerations,—not to use a harsher term,—he is at the same time painfully aware that a number of his more credulous patrons will forget his last season's bill in order to promptly remit, in advance, the exorbitant price charged for this most successful class of proprietary shams, put forth by conscienceless adventurers who have developed lying into a commercial science and made it almost respectable!

That the element oxygen has latterly established a claim to be recognized as a valuable therapeutic aid is quite generally conceded. That it has been retarded in its recognition by the charlatans who have counterfeited it is also equally clear. To obtain the remedy in a pure and reliable form, convenient for general use in the office and easy of transportation to the bedside, has been at once a desideratum and a difficulty. Notwithstanding these obstacles, within a few years its use by American physicians has increased a hundred-fold; and improved apparatus and better methods are gradually overcoming the numerous drawbacks to its still more general use. In New York City alone there are now several quite well patronized dépôts for furnishing the compressed gas to practitioners who prefer to procure their supply in this way, and thus save the time, labor, *and litter* involved in its manufacture.

With these increasing facilities the profession ought to be able to drive shoddy "oxygen" out of the market. Yet it is but one of a class, and that a very large class.

There are anti-tobacco societies, anti-liquor parties, even anti-adulteration journals; but there are no anti-nostrum associations. That there is a need for such has already been sufficiently set forth.

In this connection the profession as a whole must plead guilty of a dereliction of duty. There is no doubt but that by proper and persistent effort practitioners have it in their power to initiate a movement which would in time eventuate in wholesome changes in public opinion touching this vitally important subject.

Two things militate against any sweeping or sudden revolution in this direction: ignorance and tradition. But even these are not utterly incurable; and here permit a practical suggestion.

In these days of the rapid advance of ideas, every medical practitioner owes it to his patrons, his profession, and his conscience to antagonize three prevailing and mischievous delusions:

1. That it is economy to doctor one's self.

2. That any remedy can be good for every ailment.

3. That irregular and unlettered "doctors" who catch the public eye through advertising display owe their "unparalleled success" to the possession of chemical or other valuable secrets which are unknown to the regular profession, and unknown to chemists.

At the same time, and as complementary of the foregoing, he ought also to

inculcate a few wholesome and general precepts:

1. That to regain impaired health does not necessarily imply the use of drugs.

2. That in consulting a physician, a maximum of advice and a minimum of medicine is a consummation devoutly to be sought.

3. That the more intelligent people become, the less they assume the responsibility of deciding questions of which only a skilful medical man is competent to judge, the less they listen to the catch-penny claims of advertising charlatans, and the less money they pay out for preparations which are not ordered or vouched for by some one in whose sagacity they confide.

4. That those who decline the use of all remedies, except when prescribed by a competent physician, experience uniformly better health, expend less money at the druggist's, and suffer infinitely less from imaginary evils, than any other class.

When practitioners everywhere conclude to spend more time and effort in disseminating these and similarly axiomatic truths than in traducing competitors or wrangling over medical politics, there will be less money poured into the coffers of the wily patent-medicine sharks, less quackery both in and out of the profession, and the medical millennium will draw nigh.

491 West Twenty-Second Street.

NOTES OF HOSPITAL PRACTICE.

MEDICO-CHIRURGICAL COLLEGE, DEPARTMENT OF ORAL SURGERY.

CLINIC OF PROFESSOR GARRETSON.

EXSECTION OF SECOND BRANCH OF FIFTH NERVE AT FORAMEN ROTUNDUM.

THE patient was a lady from Oregon, suffering with neuralgia of several years' standing affecting the superior maxillary division of trifacial nerve. Remedies of every nature having been tried at the hands of some twenty different physicians, and several minor operations done at different Western hospitals, and the suffering having increased to such extent as to render it no longer endurable, the operation of excision of the nerve-trunk was proposed and gladly accepted.

On September 11 the patient was etherized and exposure was made of the anterior face of the antrum, the infraorbital nerve being dissected from the flap and caught by a bull-dog forceps. The immediately-succeeding step removed the boundary of the sinus, the surgical engine being used, while the burr, directed by the line of the nerve, quickly cut away the floor of the canal, and so permitted the branch to fall into the antrum.

Following this was the task of reaching the nerve, as it rests upon the floor of the orbit. Great care being exercised to clear the cavity of the sinus from clots of blood with which it too quickly filled, and a raspatory being used to scrape a line upon the antral roof, a dull burr was put in the place of the sharp one heretofore used, and the marked and rasped space was cut away to an extent which exposed nerve and eye-appendages. Here delay was made to show to the class at large the exposed nerve as it lay, white and shining, in the opened antrum, and could be moved about in all directions.

The final step of the operation—namely, entering the spheno-maxillary fissure—required the greatest attention and caution. The burr used was conical as to shape, fine and short as to blades, and was revolved to the extent of the power of the engine, some fifteen thousand revolutions to the minute. It being shown to the audience that absolute steadiness had been secured by means of the velocity, the antrum was again cleared of blood-clots and its posterior face made to define itself clearly in the sunlight. All being prepared in accordance with the mind and requirements of the operator, the burr was reintroduced into the cavity, and in a single moment the fissure was opened.

To insure the proper completion of so delicate and complicated a performance, the nerve was isolated and the round foramen defined by means of a delicate fenestrated probe, which, guided by the nerve it encircled, was pushed inward and upward until it struck the base of the skull. The nerve-trunk was then cut by means of a tenotome or fine curved bistoury.

This operation, perhaps one of the most delicate and least frequently attempted performances in surgery, has been thrice shown within a short time to his students by Professor Garretson.

On the third day after the operation a visit to the hospital showed the patient sitting up in a steamer-chair, chatting

comfortably with her nurse. The union of the external wound was already and perfectly accomplished by first intention. At the date of this writing, still three days later, a sponge, with which the eye was being insured against any possibility of prolapse, had not been removed.

SECTION OF SUPERIOR MAXILLA IN TREATMENT OF NEURALGIA.

The subject in this case was from Bermuda,—a lady, a private patient of Professor Garretson's, about 60 years of age. The neuralgia was persistent and severe, and of some twelve years' standing. Diagnosis as to position was arrived at through the process of exclusion. The seat of lesion was determined to be on the line of relation of the posterior and anterior dental nerves, where these lie at the base of the antrum.

The operation was performed by means of a circular saw, the lip and cheek being held out of the way and protected by means of retractors; the object being to remove all that portion of bone bounded in front by the symphysis, at the back by the tuberosity, above by the floor of the sinus, and below by the free ridge of the gum. This locality was mapped out by means of incisions reaching through the overlying soft parts to the bone. Following the incisions, and occupying the lines of the cuts, came the saw. It required scarcely an appreciable period of time for the operator to show the section in his hand to the class. The relief from pain was decided and immediate.

Nine minor cases were then shown and treated.

TRANSLATIONS.

Hydrofluoric Acid in Therapeutics.—In a recent thesis upon the therapeutic applications of hydrofluoric acid, Dr. Chevy submits the following conclusions:

1. The vapor of hydrofluoric acid mixed with atmospheric air does not produce in the respiration the accidents which hitherto have been attributed to it. It can be breathed without inconvenience in a mixture containing one to fifteen hundred parts.

2. Hydrofluoric acid is a powerful antiseptic and antiferment. A solution of one to three thousand is able to arrest fermentation in milk, urine, or soup, and to permit the preservation of meat.

3. The therapeutic employment of hydrofluoric acid against pulmonary tuberculosis, diphtheria, and in the dressing of unhealthy wounds appears to have furnished results worthy of being followed up.

4. If the diseased person be asthmatic, hæmophiliac, or emphysematous, this agent should be used with caution.

The method of disengaging the gas employed by the writer is to obtain it directly from fluor-spar contained in a leaden vessel, and the addition of sulphuric acid in excess. The diluted gas is to be inhaled cautiously; and where this had been done in several cases, the patients not only bore it well, but asked that it might be repeated.

Urinary Calculus in the Female Bladder.—Dr. Curtil gives the following as his conclusions (Paris Thesis, 1886) from a study of the subject of treatment of vesical calculus in women: (1) All things else being equal, we should always prefer a bloodless operation to a bloody one. (2) For a stone not larger than from two to three and a half centimetres we should resort to dilatation as the method of election. (3) In the case of a calculus which, although voluminous, yet is friable, in a patient whose bladder is tolerant and otherwise normal, we should select lithotrity, modified, when required, according to the necessities of the case. (4) In all other cases we should employ the hypogastric section.—*Revue de Thérapeutique Méd.-Chirurgique*, No. 16.

A New Microtome.—MM. Henneguy and Vignal showed at a recent meeting of the Paris Biological Society a modification of the Cambridge rocking microtome. In the original model it is necessary to count the notches in order to ascertain the thickness of the sections; also the direction of the embryo cannot be changed after it is fixed on the instrument. In the instrument modified by MM. Henneguy and Vignal, by the aid of an indicator moving along a graduated circle, controlled by the regulating piece, the thickness of the sections is at once ascertained. By means of a holder capable of being moved on three different axes, the pieces studied can be moved in any direction.

PHILADELPHIA, OCTOBER 16, 1886.

EDITORIAL.

ON OBESITY.

"Oh that this too too solid flesh would melt!"

LIKE other maxims, "Laugh and grow fat" is part sound, part false. Little as we may suspect it, the advice is far from being of universal application. Its wisdom and beneficence depend wholly upon this point of view. It is all very well to laugh, but the growing fat is quite another thing. It would be well for some of us, if laughter bred fat, to take our pleasure sadly. For if the fat man be a merry man, he pays for his mirth by much discomfort and inconvenience. More than this, he is in the way of dangers that miss his lean and envious neighbors. These dangers are manifold and dire; but space forbids us to describe them, or even to enumerate them. And we are the more constrained to reticence on this subject lest we might in too free discourse add aught to the weight which our fat friends are compelled to bear.

"Where ignorance is bliss, 'tis folly to be wise." Here again a maxim that is less than half true. For we feel constrained to say in all seriousness that in many a case the greatest danger that can befall a fat man or woman is to catch the present fashionable craze and undertake to become lean. Some men—and women too, if for the truth's sake we might make so bold as to say it—are born to be fat. It runs in the blood and is a family failing. Others, having acquired fat by their personal efforts, wear it until it becomes second nature and their organs are accommodated to it. In both these sorts of persons obesity has grown to be a normal condition, inconvenient and uncomfortable, it is true, and, with advancing years, in itself attended by many dangers.

To reduce it in such cases as these to any considerable extent is always difficult, and often attended by risks of the most serious kind: all of which was already known to the ancients, and is spoken of by Hippocrates and Celsus. Bantingism is out of fashion, by reason of the evils which followed its improper use; the method of Ebstein is also out of favor,—tried in the balance and found wanting,—because of the persistent gastric derangements which it often causes. Schwenninger's plan was successful with that man of iron, Prince Bismarck, but its oft-repeated little meals—day-long nibblings—play hob with ordinary stomachs.

Finally, the method of Oertel has come to the front, and is just now so much in vogue in Germany that a single word has been invented to designate this particular *Entfettungs-Kur:* namely, the word *örteln.* The peculiarities of this method, which is well known through the publications of its originator, consist chiefly in a restricted diet without fat, a greatly restricted amount of fluid, and increased muscular activity, especially of such kind as increases the action of the heart. Rosenfeld, of Stuttgart, has quite recently called attention to the dangers which attend this "cure." These are of a very serious kind, and have in some instances narrated by this observer proved fatal. They relate to the kidneys, the heart, and the nervous system. Rosenfeld found albuminuria in eight of twenty-four cases, in all of which albumen had been definitely absent before the cure. The symptoms and the microscopical and chemical characters of the urine indicated acute nephritis passing into chronic parenchymatous nephritis. Two of these cases terminated fatally. The danger as regards the heart is that, in consequence of the stress brought to bear upon it, muscular insufficiency and dilatation may be developed, with shortness of

breath, palpitation, and irregular, feeble pulse. Among the symptoms due to derangement of the nervous system are loss of appetite, *anorexia nervosa*, vomiting, gastralgia, enfeebled digestion, and stubborn sleeplessness.

Surely it is better to be fat and feel comparatively well than to run so many risks and suffer so many ills in trying to become something else than what Nature evidently intends us to be. The greatest danger to many a fat person is that he should attempt to become lean.

MAMMARY ABSCESS.

SUPPURATIVE inflammation of the mammary glands occasionally occurs in new-born children and in girls at the age of puberty. Its frequency is, however, so much greater during the periods of functional activity that it may be practically regarded as a disease of lactation.

E. Bumm* refers cases of this affection as it occurs in lying-in and nursing women, and occasionally also during pregnancy, to two groups, differing in causation as well as in their course and termination: 1, simple parenchymatous (non-infectious), and, 2, phlegmonous (infectious) mastitis.

1. Simple or non-infectious mastitis is due to the accumulation and retention of the newly-formed secretion, and differs in degree only from that physiological fulness and tension which are felt in the breasts upon the second or third day after parturition. The mammæ, being but poorly supplied with intrinsic contractile elements and wholly lacking the influence of extrinsic muscles, are less favorably arranged than the other glands of the body for the discharge of their secretions. They are dependent upon the aid of the suckling, or, in its absence, of the breast-pump. If this aid be deficient, the retention which follows may cause local and general disturbances that are, especially in women of irritable, nervous organization, of some moment. The temperature may reach 102.8° to 104° F.; the breast is full, hard, and painful; red streaks extending in the direction of the axilla may indicate inflammation of the lymphatics. But the tendency after massage and suction is to dispersion and resolution, and only exceptionally is there necessity for evacuation by an incision through the skin. Even then the discharge is not pus, but milk in process of inspissation and disintegration of the globules, and, with rare exceptions, it is free from bacteria. Here we have the familiar "weed" of the old nurses.

2. But in phlegmonous or infective mastitis we have a very different and much more troublesome affection to deal with. The line of separation between the two conditions is sharply defined. In fact, they have nothing in common except the same anatomical seat, nor can there be any question as to the development of the graver out of the milder malady.

Phlegmonous mastitis occurs more than twice as frequently in primiparæ as in multiparæ; much more frequently in women who are nursing than in those who are not. It begins in by far the greater number of cases in the course of the first month after accouchement; lesions of the nipple usually precede it; and, finally, a part only of the breast is commonly implicated at first, and that part is usually the undermost or the under and outer part. Errors in diet, colds, worry, mechanical irritation, are, singly or together, quite incapable of causing this form of inflammation. It is due to the presence of specific pyogenic microbes. These cocci are found sometimes arranged in clusters (staphylococci), sometimes in chains (streptococci), and are to be distinguished from other microbes of similar form by the peculiar appearance of their pure cultures and by their active growth, while the energy with which they take up and retain aniline dyes

* Volkmann's Klinische Vorträge, No. 282.

renders their study in the tissues comparatively easy. The distribution of these organisms is so wide and abundant that their contact with the nipples is almost unavoidable. Any want of the most thorough cleanliness, any abrasion, maceration, or loss of epithelium, opens the way for the infection of the deeper structures of the breasts. And it is here that the long-recognized relation between lesions of the nipple and phlegmon of the breast finds its explanation. The disproportionate frequency of the latter affection in primiparæ is also made clear, when we consider their greater obvious liability to nipple-lesions. The invasion may be subcutaneous, and by way of the lymph-vessels deeply into the interstitial connective tissue of the gland, or much more commonly it is by way of the milk-ducts directly into the parenchyma. Infection once set up, milk-retention, by widening the ways of access to the deeper parts, favors the extension of the pyogenic inflammation.

The positive knowledge of the etiology and true pathology of phlegmonous mastitis gained by bacteriological studies has less bearing perhaps upon the treatment, which must still be conducted in accordance with accepted surgical procedures, than upon prophylaxis. The hardening of the surface of the nipples by daily bathing with cold water and gentle frictions during the later months of pregnancy, and their systematic bathing after nursing, long advised by cautious midwives, have now more than a mere empirical basis. To avoid all maceration and guard them by vaseline or oil while yet sound, and to heal without delay each fissure or abrasion so soon as it appears, are measures no longer to be lightly neglected. "Sore" or "cracked" nipples are troublesome enough in themselves: in the light of their relation to "gathered breast" they acquire a new and serious importance.*

* Dr. Ernst's article on another page will be read with interest in this connection.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE date for the reopening of the medical schools in England is now close at hand, and with the resumption of teaching comes a general revival in the interest of medical work. Within the last three or four years great improvements have been made by several of the smaller schools in their buildings. At Charing Cross, St. Mary's, and Westminster new school-buildings have been erected at very considerable cost: an immediate increase in the number and also—it is said—in the quality of the students followed the provision of theatres and laboratories adequate to the needs of modern medicine, so that the staffs of those hospitals by whom serious pecuniary responsibilities must have been undertaken have already begun to reap their reward. This year the arrangement made with the Science and Art Department comes into force: under it the students who enter the medical schools attached to the Middlesex, Charing Cross, St. George's, and Westminster Hospitals will receive instruction in preliminary science in the Science Classes of the Department at South Kensington. The student pays a composition-fee to the school of the hospital of his choice, and the school pays a capitation-fee to the department. The scheme is generally considered to be a move in the right direction: the attempt to keep up a complete series of classes for instruction in the preliminary sciences put a severe strain upon the resources of the smaller schools, and it has been very commonly said that not only the teaching but the apparatus has not been up to the mark. The great State Department at South Kensington commands not only most perfect apparatus, but teachers of the highest ability. Professor Huxley was for many years its guiding spirit, and, though ill health has compelled him to relinquish all work, he has left pupils worthy of his reputation. This arrangement between these medical schools and the Science and Art Department is only temporary. In the course of years it is possible that they may combine together to erect and maintain a combined school for preliminary science, which would be under the direct control of a joint committee. The success of the scheme will probably have an injurious effect upon University and King's Colleges, especially upon the former. For a long time University College had everything its own way, and the services which it rendered to biological science can never be forgotten, and indeed mark an epoch in the history of science in this country. First Cambridge, and now Oxford, has established classes and laboratories which are attracting the cream of the students: this scheme of the

smaller London schools will further diminish the attractions of University and King's Colleges, and the larger schools in London are now alive to the importance of having good science schools. With this object the school-buildings of the London Hospital, for instance, have been almost entirely rebuilt, and enlarged to thrice their former capacity. The move to provide residential colleges for medical students is also gaining ground; and if the scheme for obtaining a charter enabling the combined Colleges of Physicians and Surgeons to grant degrees is successful, as there is no reason to doubt, then the supremacy of London as the chief British medical school, now seriously threatened by Edinburgh, will become more firmly established than ever.

A circular recently published containing a sketch of the arrangements already made for the International Medical Congress next year is in one respect a disappointing document, for it shows that, as a rule, the leading men in this country in their several departments have either not been asked to hold office or have declined the honor. Such names as those of Professors Annandale, Burdon-Sanderson, McCall Anderson, Richard Quain, Erichsen, and T. R. Fraser, of Sir William MacCormac, and Drs. Klein, Charles West, Eustace Smith, and Mr. John Simon, give weight to the list in the eyes of Englishmen, but it would not be difficult to strengthen it very materially.

The British Dental Association, a young but flourishing institution, with nearly seven hundred members, held its annual meeting last month. Most of the papers read were of purely special interest, but two were of more general significance. Mr. Fisher, of Dundee, again urged the advisability of providing compulsory attention for the teeth of school-children, and Dr. George Cunningham, of Cambridge, discussed with much acumen the "Relation of Dentistry to the State." The working and poorer classes in this country almost entirely neglect the care of their teeth; among the patients who come to the out-patient departments it is rare to see anything approaching a perfect denture. Dr. Cunningham examined the mouths of a hundred young men who presented themselves consecutively for service in the army at a recruiting-station in London: he found that seventy per cent. were suffering from inflamed and ulcerated gums, twenty-seven per cent. from chronic abscess, that on an average each man had lost or would be the better for losing more than three teeth, and had also four carious teeth that could be stopped. As all these recruits were young men, and as about sixty per cent. were accepted as fit for service in the army, it is safe to conclude that they afford a criterion of the state into which the teeth of the whole class from which they are drawn are habitually allowed to fall. There are hundreds of dentists who are willing to stop teeth for a very small fee, but the working classes appear not to be sufficiently alive to the advantages which conservative dentistry could confer on them to bé willing to expend even the small sums demanded: they seem to prefer to put off the evil day until extraction is the only possible treatment; a small percentage subsequently obtain false teeth, which, however, do not seem to be often well fitted. With that very large and, it is to be feared, increasing class who find the struggle for existence too keen to leave any margin for dentists' fees, however modest, extraction is almost the only treatment. The Dental Hospitals will stop the teeth of patients coming with a subscriber's letter, but this useful work is on so small a scale that it produces but little apparent effect on the general population. Dr. Cunningham sought to show that it would be worth while, from the pecuniary point of view alone, for the state to give attention to the conservation of the teeth of the young men entering the army and navy, at least: a trained soldier, and still more a trained sailor, is an expensive product, and it cannot be doubted that the state loses every year a large sum by the ill health directly or indirectly traceable to painful teeth or imperfect dentures. It is, of course, very difficult to prove the extent of this loss, but, as the richer classes in this country are very assiduous in the care of their own teeth, it ought to be a comparatively easy task to convince our legislators that it would be advisable to establish dental departments on a modest scale in connection with the medical departments of the army and navy.

A project is now on foot which may have a most beneficial effect on the progress of the science of hygiene in this country. Soon after the death of Dr. Parkes, Professor of Hygiene in the Army Medical School at Netley, and author of the well-known book, a meeting of his friends determined to perpetuate his memory by bringing together a collection of sanitary apparatus. The Parkes Museum has been kept together ever since, and a library of some importance has been brought together; but the pecuniary position of the undertaking has never been satisfactory, in spite of the disinterested efforts of most of the leaders in practical sanitary work. Another body, the Sanitary Institute of Great Britain, came into existence at about the same time as the Museum, and has gradually fought its way to general recognition. It holds every year a Congress in some provincial town, and during the Congress an exhibition of novelties in sanitary appliances is organized and kept open for about three weeks; the Institute also grants diplomas to District Surgeons and Inspectors of Nuisances after examination, and publishes an annual volume of Transactions. It had long been felt that these two institutions could work

much more effectively and at a greater economy in time and money if they could be amalgamated. This process is now in progress: the constitution of a new body to combine the work of the Parkes Museum and the Sanitary Institute has been provisionally approved by the members of both, and I understand that those who know most of both look forward hopefully to a satisfactory arrangement before very long.

A medical question of international importance—the present unsatisfactory position of ship-surgeons—has recently attracted some attention in the lay press. The greater part of the transatlantic passenger trade, and almost all the trade to India, Australia, New Zealand, and the Cape of Good Hope, are at present in the hands of English companies, whose fleets are officered by Englishmen. Some of these enormous boats afford a temporary home to a very large number of persons,—travellers, emigrants, and seamen; the passengers and emigrants at least are often placed under circumstances of great discomfort, involving some danger to health, and statistics appear to show pretty plainly that the mortality on board transatlantic liners is excessive. Such being the case, it is much to be regretted that there is practically no sort of control over the appointments made by the companies to the post of medical officer in charge of these passenger-ships. At present the only requirement is that the individual thus appointed shall hold a diploma qualifying him to practise in Great Britain or Ireland. Ship-owners as a rule do not, it is said, favor independence of character: a surgeon who will go through the routine prescribed by the Board of Trade, who shuts his eyes to deficiencies in the sanitary arrangements, who will accept small pay, and, above all, who will make no complaints, is the officer most desired; if in addition he is sober and makes himself socially agreeable to the passengers, then he will be all that any ship-owner could wish a surgeon to be. Official inquiry has left no doubt that the regulations of the Board of Trade, especially those connected with the provision of proper hospital accommodations on board, are systematically neglected; representations bearing on this question and giving well-authenticated examples of the abuses which exist have been made to the Board of Trade and also to the Royal Commission on Loss of Life at Sea. This Commission, however, has not recently given any signs of life, and, in the impotent state to which politicians of all shades of opinion have been reduced by the events of the past year, it is highly improbable that any useful ameliorative legislation will be possible perhaps for years. The advocates of reform urge that the medical officers of passenger-ships ought to be independent of the caprices of owners or captains; they urge that a Mercantile Medical Marine Service should be formed, and placed under the control either of the Board of Trade or of the Local Government Board, which is already charged with the supervision of Port Sanitary authorities. The surgeon of a ship, especially of an emigrant-ship, is not only a medical but a sanitary officer, and the proper discharge of his duties in the latter capacity is a matter of great importance to the United States and other countries which receive immigrants in large numbers. The Australian colonies long ago appreciated this, and established a Colonial Emigrant Medical Service, which attracted a very competent class of men. It is now asked that the British government should establish a Mercantile Marine Medical Service on the same lines, and it is urged that if the members of such a service were assured of adequate pay, promotion, and pension, and were made responsible in sanitary matters to a government department, a thoroughly good class of men would be led to join, to the advantage alike of passengers, emigrants, owners, and of the countries concerned in the trade.

The death of Dr. James Wakley, from epithelioma of the tongue, occurred on August 30. Since the death, in 1862, of Mr. Thomas Wakley, M.P., the founder of the *Lancet*, Dr. James Wakley had acted as editor of that influential journal. He was seldom seen in the medical world of London, but had the power of attracting to himself a band of zealous and enthusiastic workers: by their aid he had more than maintained the high standard of excellence reached during his father's conduct of the *Lancet*.

DAWSON WILLIAMS.

September 18, 1886.

JAPAN.

THE CHOLERA IN JAPAN.

THE principal topic of medical interest in the capital has been for some time past the progress of the cholera in this country. Although Asiatic cholera can hardly be said to be epidemic in Japan in the sense that it has recently been epidemic in some European cities, yet, nevertheless, having stricken down nearly one hundred thousand persons in less than three months, of whom over half have died, it is not to be wondered at that the presence of such a disease should prove a source of great anxiety to the people, and demand every possible combative measure to be taken upon the part of the government and the medical profession. That the people are thoroughly alarmed there can be no doubt, as one is constantly meeting persons upon the streets with carbolized handkerchiefs to their noses and bottles of cholera-mixture in their hands. It is fortunate that such a wholesome dread exists, as it leads to more care being taken as to diet and drink; while on the part of the government every precaution is being ob-

served against further spread, and present arrangements for the care and treatment of cholera-patients are being perfected.

The cholera, although it has carried off so many citizens, has not proved an unmitigated calamity. The majority of deaths has been among the lower classes, with only here and there one of the gentry; but the government and people have become thoroughly awakened to the necessity of making immediate improvements in the water-supply and drainage of the larger cities, as well as in laws governing tenement-dwellings and the sale of deleterious foods. Not that these improvements have not been going on for the past ten years, but that they should be pushed faster.

Tōkyō as a capital city is far ahead of any Eastern capital in its sanitary arrangements, and if one were to compare its death-rate with those of some Western cities the result would not be greatly against it, as the rate, I think I am safe in saying, is seldom above twenty-six per thousand.

The city, including within its urban and suburban jurisdiction a population of over 1,200,000 within a radius of about six miles in every direction, has six thousand acres in public parks, and probably as many more acres in temple-grounds; the former giving one acre to about every two hundred inhabitants, which is about the same proportion as in London, and is exceeded only by Paris, Vienna, Washington, Dublin, and Boston; while it is equal to that of Chicago, and stands above that of New York, Berlin, Philadelphia, Baltimore, and San Francisco.

It has a very extensive water-supply, which was undoubtedly originally good, but, as has been found upon analysis to be the case, is at the various points of delivery very much deteriorated from passage through miles of wooden pipes. The two supplies of the city are known as the Kanda and the Tamagawa canals, with the former of which there are connected about twenty-nine miles of wooden pipes, and with the latter about thirty miles, or nearly sixty miles in all, supplying, it is stated, about forty million gallons of water daily through some eight thousand wells and many overflows. If all this water were used, there would be a proportion of about thirty-three gallons per head, which, taking twenty-six gallons per head as a standard,—the allowance made by the engineer of the new water-works for Yokohama,—would be a liberal supply; but it is probable that the actual supply per head per diem is not as abundant, although there are numerous surface-wells besides.

The drainage is mostly through surface-drains, some of which are washed with water from the aqueduct-overflows, and are thus kept tolerably clean.

It will be seen from the above that the water-supply and drainage of Tōkyō are two very important factors bearing upon public health in the city, so that it is probable that the present epidemic will have the effect of hastening the laying of iron pipes instead of the leaky wooden ones, and of causing the drains to be rebuilt; in which case, as I have said, it will not prove an unmitigated calamity.

Whenever such improvements have been made, we may hope, in Tōkyō at least, to suffer less from cholera epidemics than hitherto. It has been stated that statistics of this and previous epidemics in Japan show that whenever an epidemic strikes a town it does not leave it until at least one per cent. of the inhabitants have been carried off by the disease. If this be true and the drinking-water be the principal means of infection, we may hope for future immunity, having before us the result of the introduction into Glasgow of Loch Katrine water in place of that from the Clyde, before which and during the epidemics of 1832, 1849, and 1854 the mortality from cholera was twelve per thousand, while it amounted only to .16, or one-eightieth, thereafter in the epidemic of 1866.

The latest returns of the cholera show that since its beginning to the 6th of September 97,897 cases have occurred, with 61,041 deaths: or about 62½ per cent. of deaths. The highest number of cases is reported from Osaka: 17,456 cases with 13,296 deaths in urban districts, and 10,473 cases with 8237 deaths in the suburban districts, making the number of cases in both urban and suburban districts 27,929, and the number of deaths 21,533. Tōkyō has already had 9140 cases with 5749 deaths in the urban districts, and 8110 cases and 5284 deaths in the suburban districts, making 17,250 cases in all, with 10,973 deaths.

The *Sei-I-Kwai Medical Journal* published September 4 contains the following editorial:

"The present epidemic may perhaps be looked at, following so close upon that of last year, as the continuation of the epidemic of 1885, in which, from August 23 to November 30, 11,927 cases occurred, with 7152, or 59.96 per cent. of deaths, although there were only sporadic cases of cholera in the country between the end of one epidemic and the outbreak of the other.

"If compared with previous epidemics, its resemblance to that of 1879 will at once be noticed. This epidemic of 1879, which was preceded by a milder epidemic (1877), began on the 14th of March, and only gained force early in July, reached its climax in the week ending August 28, diminished greatly immediately afterwards, and by the middle of September was under control; after which there was but one exacerbation, which occurred in the first week in November, the epidemic gradually dying out and disappearing in the month of December following. The total nnmber of cases in this epidemic was 162,637,

of which 105,786, or 65.04 per cent., died. Referring to the tabular statement published by the Sanitary Bureau, it appears that the greater number of cases and deaths occurred before the end of August, and from that time onward until the end of the year the epidemic gradually lost force. Comparing the death-rates of the two epidemics, it will be noticed that the rate of 1879 was 65.04, while that of this year is thus far 63.55, or one and a half per cent. lower. We may therefore feel encouraged, as the number of cases and deaths has only been two-thirds of the number of cases and deaths at the same stage of the epidemic of 1879, and also as the death-rate is somewhat lower; and we may reasonably hope that the force of the epidemic will soon be broken. Certainly the reports from Yokohama and other provincial towns are encouraging, the number of new cases having been reduced to less than a dozen daily. In the capital, however, the epidemic still continues to rage, the number of cases having been slowly increasing, with a corresponding number of deaths, up to the 25th; the number of cases, as shown below, is now about two hundred to three hundred daily, with from one hundred and fifty to two hundred deaths. The authorities are leaving nothing undone to check the epidemic, and have undoubtedly, in spite of the bad influence of great heat and dry weather, kept the disease from spreading to the same extent that it had at the end of August in the epidemic of 1879."

It may therefore be reasonably hoped that the worst is over, although the number of cases in Tōkyō reached three hundred and fifty, with two hundred and twenty-four deaths, on the 1st instant.

One of the good results of the present epidemic has been the stimulus it has given to the careful study of the disease and the perfection of means to prevent its spread. The Japanese Health Society has published minute descriptions of the malady and the principal methods of treatment; while, with other societies, it has widely disseminated this information in popular form. The government has also issued directions respecting the management of the disease, which are posted in conspicuous places. Patients suffering from cholera are, as soon as reported, unless they can in the judgment of the police be properly cared for at home, taken upon litters to the cholera-hospital, where they have every attention and the best of medical skill. The houses where cases have occurred are usually quarantined for a week thereafter, and the bedding and other articles used by the patient or likely to have been infected are burned. In case the patient dies, his body is cremated.

Nearly all the wells in the city have been examined and their waters analyzed, and, in case of their being unfit for drinking purposes, their use for such purposes is prohibited.

It will be seen from the above that the authorities are thoroughly in earnest, and are bringing every resource to bear in stamping out a disease which had threatened to become a scourge to Japan.

Tōkyō, September 9, 1886.

PROCEEDINGS OF SOCIETIES.

THE AMERICAN GYNÆCOLOGICAL ASSOCIATION.

(Continued from page 32.)

Second Day.

AT the opening of the morning session the Secretary, Dr. JOSEPH TABER JOHNSON, presented a paper contributed by Dr. JOHN GOODMAN, of Louisville, Kentucky, and read it in the absence of the author. It was entitled

ERGOT AFTER LABOR.

The practice of giving ergot has been sanctioned by the highest authorities. It is generally claimed that it acts by preventing after-pains, by hastening involution, preventing hemorrhage, and averting septic poisoning. It will be admitted that if its good results could be obtained without incurring additional danger it is worthy of being used, but if there is added danger it should be investigated. In one case uterine spasm and ergotism followed the administration of a single drachm of the fluid extract after confinement. On the third day a slight fever began, which continued for a week; there was no secretion of milk. Though previously prolific, the patient never afterwards conceived. A second case was a primipara, who had been delivered by forceps. Ergot was given as before. On the third day retention of urine required the introduction of the catheter; on the sixth day fever set in, with tenderness of the abdomen, offensive lochia, and a clot of blood was expelled. In spite of treatment, the patient died with septicæmia on the fourteenth day after labor. The explanation of the case is that the uterus was made to contract firmly upon a clot of blood, which, unable to escape, underwent putrefactve decomposition, and the products were absorbed, causing septicæmia. Such attacks the author had noticed a number of times, and thinks that others must also have seen them, but attributed them to malaria or milk-fever. The fever lasts from one to five days, and he thought must be due to some action of the ergot upon the system at large.

That ergotism thus early introduced can hasten involution he considered an absurdity; even if it could be hastened, he questioned its desirability. Involution is a normal process, like digestion, and it must proceed according to physiological law. The routine administra-

tion he condemned as being as unphilosophical as it would be to give a dose of pepsin after each meal. The most marked case of subinvolution he had ever seen occurred in a case in which a midwife had given ergot freely during labor. The action of ergot upon the muscular tissue of the uterus and blood-vessels he regarded as antagonistic to the normal process of involution after labor.

The only benefit which could accrue from the administration of ergot after labor is the prevention of hemorrhage. His rule was never to give ergot unless post-partum hemorrhage was imminent. The best method of administration he believed to be by hypodermic injections of ergotine, given every fifteen or twenty minutes until the effect is produced.

The PRESIDENT called upon Dr. BARKER to open the discussion.

Dr. FORDYCE BARKER replied that he had very little to say, except that this was by far the most original paper that he had ever heard read before the Society: original in its conclusions and original in its reasoning. It is a subject which has been frequently discussed, and upon which each have their own opinions made up, and therefore hardly requires discussion.

Dr. THADDEUS REAMY said that he would anticipate the publication of a paper on this very subject, which he had prepared to read before the annual meeting of the Cincinnati Academy of Medicine, sufficiently to say that in it he had gone over the question, and had condemned the routine administration of ergot in confinement as unnecessary and injurious. The contraction produced by ergot is a tonic spasm of the uterine muscle, and is very different from the normal rhythmical contraction which should occur after labor. He felt assured that in the course of the next six or eight years there will be an entire revolution in the obstetric procedure in respect to the administration of ergot after labor.

Dr. BARKER stated that in the absence of the author of the paper he did not wish to speak when called upon to open the discussion, but since the same views have been expressed by the President he thought that they should be controverted.

Dr. GOODELL said that he was not an extreme partisan of ergot, but he could not accept the conclusions of the paper. He believed them to be based upon insufficient experience. The cases reported are explainable upon other grounds. The first was one of fibroid polypi; the second, of septicæmia. There is no evidence that ergot was responsible for the accidents in either case. The lecturer invokes "Dame Nature," but forgets that we are living not in a natural state, but under artificial conditions. After-pains rarely occur in primiparæ. In twenty-five hundred cases of obstetrics he had never seen any bad results from the exhibition of ergot; the single dose of ergot after labor can exert but little influence upon involution, which is a process of fatty degeneration. In these days there is less danger of septicæmia since we have learned the use of antiseptics, and we do not need to give ergot to prevent it. The principal utility of the drug is in preventing hemorrhage.

Dr. ENGELMANN still holds the views that he expressed in a paper read at a former meeting with regard to the dangers of the abuse of ergot; he believed that hot water, the faradic current, and the other resources of antiseptic midwifery would enable us largely to dispense with the use of ergot after labor. In spite of what has been said and written, ergot will remain a valuable remedy, and he would not venture to say because it had been abused that it should be abolished. The injury which has been caused by it has been due to the abuse and not to its proper use.

Dr. PARVIN called attention to the fact that it had been assumed in the discussion that ergot always produces spasm of the uterus; he believed it to be a question of dose. Nothing is better established in therapeutics than that small doses of ergot may produce tonic contraction of the uterus. He refused to admit the argument that ergot should never be given prior to the emptying of the uterus, since the practice of two men who have been most successful in the treatment of placenta prævia—Dr. Ellwood Wilson, of Philadelphia, and Dr. Murphy, of England—has been to use ergot. Again, in cases of lingering labor where no obstruction to delivery exists, small doses of ergot will produce expulsion of the child. If women were perfect in structure and function, labor would be a normal process and obstetricians would not be required; but, the contrary being the case, the argument of the lecturer falls to the ground: nature in civilized life requires the assistance of art. By the use of ergot he had found that involution was not prevented, but hastened.

Dr. REEVE wished to enter a similar protest against the argument of the paper.

Dr. SKENE asked, if the deductions of the paper were accepted, whether it would tend to advance the obstetric art or put it back about seventy-five years. He believed that experience had proved the usefulness and limitations of ergot. The results reported from the use of ergot in the West were certainly different from those in the East. He hoped that the prediction of the President would not be fulfilled, but that in five years he will forget all that he has said about ergot.

Dr. WILLIAMS, of Boston, believed that ergot has a function to perform in obstetric medicine. In an experience of thirty-five years he could not recall a single case where after using it he had regretted doing so.

The President's address was then delivered by Dr. THADDEUS A. REAMY, of Cincinnati.

THE ADDRESS OF THE PRESIDENT.

At the beginning of the second decade of the Society, the speaker could not but congratulate the Fellows upon the enduring monument they had erected to the science of gynæcology in the ten volumes of Transactions which had been published. The work done by the Society and individually by the Fellows had contributed largely to advance in the departments of obstetrics and gynæcology.

After pausing to pay a brief tribute of respect to the memory of Dr. Albert Holmes Smith, of Philadelphia, an ex-President of the Society, whose death had oocurred during the year (and an appropriate biographical sketch of whom would be contributed by Dr. Parvin to the Transactions), he took up the principal subjects of his address. Ovariotomy has reached such perfection that Tait can report a series of one hundred and thirty-nine cases without a single death. But there is a danger that the gravity of the operation may be underrated,—undertaken by those who are unaware of the essentials to its successful importance, —and thus ovariotomy be brought into disrepute. Is the operation for removal of the ovaries for supposed beginning cystic degeneration, cirrhosis, catarrhal salpingitis, chronic catarrh of the tubes, stenosis, congestion, enlargement, always justifiable? He thought not. Sinless ovaries have been sacrificed, and women mutilated who might have recovered by hygienic treatment, electricity, vaginal irrigations, local applications, and rest. Statistics of Dr. Coe show that there has been a little too much enthusiasm manifested for unsexing women. Much of the pathology has been constructed after the operation in order to excuse the removal of ovaries and tubes. He applauded the conservatism of Schroeder in leaving the undiseased portion of the ovary where possible. While as a Society and individuals he called upon his hearers to do all in their power to proclaim and practise against this unsexing enthusiasm, and to endeavor to determine its limitations, at the same time he would not wish to be understood as saying one word against spaying in properly-selected cases. Abdominal surgery has conferred no greater blessing nor shone with brighter lustre than in the rescue by these operations of certain subjects, curable by no other means, from death, or from a life worse than death.

The triumphs of ovariotomy have stimulated abdominal surgery, and have demonstrated the fallacy of the old ideas of peritoneal intolerance. One of the recent advances of this character is seen in the adoption of laparotomy for suppurative peritonitis, which has been performed with encouraging results in England.

Alexander's operation is still on trial, but, as it rests on sound principles, it seems probable that it has a future. The results, however, have not been very promising thus far, it must be confessed. Even in the hands of experts it has signally failed, and the mortality is variously stated at from one to six per cent., and many of those apparently relieved by the operation show relapses.

The means for the recognition of early signs of pregnancy are still lamentably defective, and the attention of the Fellows was directed to its importance. Diagnosis other than by surgical means he feared had recently been too much neglected. High diagnostic skill is the first essential to successful practice,—"qui sufficit ad cognoscendum, sufficit ad curandum."

Medicinal therapeutics have not received as much attention as they should have done in the proceedings of the Society. The discovery of some agent with a specific action upon the ovary might prove an ovarian saviour. But this neglect of medicine in this field is not confined to the Society: it is one of the derelictions of all countries, to which attention had been well directed by Dr. Meadows in his address on obstetrics before the last meeting of the British Medical Association.

Electricity has a place in our therapeutics, and deserves an intelligent trial at the hands of the profession. It has fought its way to the front through a most obstinate scepticism, bred largely of ignorance of the indications for its use and mode of employment. In the treatment of extra-uterine pregnancy, it has been demonstrated beyond a doubt that it is the safest and most efficient treatment yet proposed for this condition. It is worthy of note that this treatment was first employed and its value demonstrated in this country by Dr. J. G. Allen, of Philadelphia.

In the treatment of uterine fibroids ergot has been given with commendable enthusiasm and patience, especially by Apostoli, with very encouraging results. He had himself seen admirable effects with regard to arresting growth in these cases with its aid. Notwithstanding the brilliant results reported from the practice of Keith, the question may still be asked whether hysterectomy for uterine fibroids is justifiable. The fact that the disease has a brief active life and of itself rarely kills suggested a negative answer to the mind of the speaker.

Cases of severe dystocia present difficulties and dangers which have hitherto been thought to require craniotomy. The improvement in hygiene of childhood, thus preventing deformity, and the development and perfection of the Cæsarean operation, and its modifications by Porro and Müller and Thomas (laparo-elytrotomy), the resort to premature labor, turning, improved forceps, have each contributed largely to diminish the proportion of cases requiring interference. The Sänger-Leopold operation will give as satisfactory

results here as it has abroad when it is done deliberately, early in the labor, and as a primary measure. As the result of recent advances, it does not require a seer's vision to declare that in the near future craniotomy will be abolished, and the instruments for its perpetration relegated as curiosities to museum-shelves.

The total extirpation of the uterus for cancer has experienced a renaissance from the successful results reported by German operators. The most rational method for its performance was devised by Dr. S. C. Lane, of California. In the opinion of the speaker, the operation is justifiable only in rare instances where the disease is confined to the body of the uterus, the cervix and vagina remaining comparatively free. It is undoubtedly justifiable in all cases of spindle-cell sarcoma of the body.

With regard to the etiology of cervical epithelioma, he committed himself to the belief that the cervical traumata of parturition strongly predispose to the development of carcinoma. In an experience of thirty years, with many hundreds of cases, he had seen but three cases of cervical epithelioma in the virgin. Emmet's operation for restoration of the cervix for manifest fissure is therefore justifiable on the ground of prophylaxis against malignant disease, if on no other.

In conclusion, the speaker discussed the curette, and recited cases where bad results had followed its use. He warned his audience especially against its use immediately after the removal of tents of tupelo or laminaria. He now uses rapid dilatation in preference to tents, and employs the curette afterwards if required. He then read the report of a remarkable case in which the copper curette by accident penetrated the uterine fundus without being followed by peritonitis or other symptom of disorder: the patient is still living.

After the termination of his address, the President strongly advocated the adoption of the proposition for the Society to join with the Surgical Association and other special organizations in a Congress to be held at Washington.

A vote of thanks was tendered the President for his interesting address.

MATERNAL IMPRESSIONS.

Dr. FORDYCE BARKER, of New York, read a paper in which a number of instances, both among the lower animals and in man, were cited in which emotional and physical impressions affected the development of the fœtus or the structure of the child.

Drs. BUSEY and BILLINGS discussed the paper, and claimed that if a law exists it must be universally applicable when the conditions are identical. It is necessary to ascertain these conditions in order to discover the law. At present no such law is known to science.

Dr. GOODELL had observed some peculiar coincidences which he could not explain, but was not willing to admit that a relation of cause and effect had been demonstrated to exist.

On motion of Dr. CHADWICK, a committee of three was appointed on this subject, to report the results of their investigations at a future meeting of the Society.

Dr. JOHN BYRNE, of Brooklyn, New York, read a paper describing the

TREATMENT OF PROCIDENTIA UTERI BY THE GALVANO-CAUTERY.

Permanent and satisfactory results in cases of procidentia uteri can only be obtained by amputation of portion of the entire cervix, added to operations upon the vagina or perineum which in themselves would be inefficient except in so far as they present obstacles to vulvar protrusion. The object of the paper was to direct attention to the important gain obtained from the alterative effect of the inflammatory processes which result in a remarkable degree when the galvano-cautery is employed in performing amputation of the cervix. In a case of extreme procidentia with prolapse of the vesico-vaginal wall, complete restoration to health followed the amputation of part of the cervix in this manner. Nine cases in all had been treated with the galvano-cautery; in three partial amputation had been performed. In six others linear cauterization alone was required.

Dr. GEORGE J. ENGELMANN, of St. Louis, read a paper on

ELECTRICITY IN GYNÆCOLOGICAL PRACTICE.

The difficulties which had beset the introduction of this agent in uterine surgery have now been surmounted, and the indications for its employment are being better defined by experience. The numerous conditions in which it had been used with reported advantage were mentioned. In obstetrics it is useful in uterine inertia during or after parturition, in cases of weak and irregular labor-pains, in post-partum hemorrhage and subinvolution, in paralysis of bladder or rectum after delivery, and in checking the development of the fœtus in extra-uterine pregnancy. Acute inflammation is the only contra-indication to the employment of electricity; it may, with proper care, be employed in subacute inflammation of the pelvic organs.

Dr. W. H. BAKER, of Boston, read a paper on

ELECTROLYSIS IN GYNÆCOLOGICAL PRACTICE.

The treatment of uterine fibroids may be successfully accomplished by the galvanic current, and the exudation in chronic pelvic cellulitis may also be removed by the same means. His conclusions were: (1) Electricity

is a useful agent in the treatment of certain cases of fibroid tumors of the uterus, as well as chronic circumscribed perimetric affections. (2) When applied to fibroid tumors of the uterus, electro-puncture is the most rational and efficient method. (3) In these cases it should not be applied too frequently. (4) Cases of perimetric affections treated by electrolysis require careful selection, with especial regard for the absence of acute symptoms.

A general discussion upon electricity in gynæcological practice, as well as obstetrics, occupied the remainder of the afternoon session.

Third Day.—The President in the chair.

Dr. JAMES B. HUNTER, of New York, read a paper on

PERSISTENT PAIN AFTER ABDOMINAL SECTION.

The causes of pain referable to ovaries, tubes, and peritoneum existing prior to operation, and those which might persist or develop subsequent to abdominal section (hernia, painful cicatrix, etc.), were considered in detail. The lecturer recommended that cases in which pain had existed prior to and had demanded the operation should be carefully watched for any return of the symptoms for at least two years subsequent to it. Peritonitis of any degree requires treatment not more for its immediate consequences than for its remote dangers. With regard to secondary operations for the relief of pain, experience has shown that they only occasionally afford relief and rarely effect a cure. In conclusion, he recommended that a guarded prognosis be given in all cases where abdominal section is undertaken for the relief of pain.

The paper was discussed by Drs. SKENE, SUTTON, WYLIE, BATTEY, H. P. C. WILSON, MANN, and J. TABER JOHNSON.

THE BLUE DISCOLORATION OF THE VAGINAL ENTRANCE AS A DIAGNOSTIC SIGN OF PREGNANCY

was the title of a paper by Dr. JAMES R. CHADWICK, of Boston, Massachusetts. He believed that, when present, this discoloration, seen more particularly on the anterior wall and about the urethral orifice, is of decided value: it is absent in about one-third of the cases during the first three months. Its absence cannot be accepted as negative evidence of the existence of pregnancy.

In the discussion, participated in by Drs. EMMET, PARISH, H. P. C. WILSON, ENGELMANN, SKENE, and JOHNSON, the presence of this appearance in some cases of morbid growths of the uterus or its appendages was mentioned, and the general opinion appeared to be that no positive sign is at present known which will enable us to make a diagnosis of early pregnancy.

The President-elect was introduced, and made a brief address, regretting that he was imperatively called to New York and could not wait until the close of the session.

In the afternoon the Society was called to order, Dr. REAMY in the chair.

PRESENTATION OF SPECIMENS OF DISEASED OVARIES, AND ALSO FROM THREE CASES OF SUPRA-VAGINAL HYSTERECTOMY.

Dr. R. STANSBURY SUTTON, of Pittsburg, exhibited specimens and detailed the histories of several cases of oöphorectomy and three cases of hysterectomy by the supravaginal method. The latter operation, when undertaken for the relief of uterine fibroids, he considered rarely justifiable. Where hemorrhage is great and uncontrollable, and the patient is rendered a hopeless invalid otherwise, the question of operation comes up for serious consideration. The cases in which it is required are, however, comparatively few.

Remarks upon the paper were made by Drs. REEVE, WILSON, WYLIE, and REAMY, and the reader of the paper closed the discussion.

Dr. WILLIAM H. PARISH, of Philadelphia, read a paper on

THE HIGH MORTALITY OF RECENT CÆSAREAN OPERATIONS IN THE UNITED STATES.

A study of the statistics of the operation of Cæsarean section in this country, as prepared by Dr. R. P. Harris, reveals the startling fact that within the last five years the mortality has apparently steadily increased. The causes for this state of things are two: (1) Delay in resorting to the operation; and (2) Attempts at delivery prior to the abdominal section.

The paper was discussed by Drs. REEVES JACKSON, BAKER, JOHNSON, and the PRESIDENT.

An obituary of the late Albert H. Smith, prepared by Dr. THEOPHILUS PARVIN, was read by title and ordered to be printed in full in the Transactions.

At the business meeting the following were elected to active fellowship: Charles M. Green, M.D., of Boston; A. F. A. King, M.D., of Washington, D.C.; E. C. Dudley, M.D., of Chicago; A. W. Johnstone, M.D., of Danville, Kentucky; H. Marion Sims, M.D., of New York; B. F. Baer, M.D., of Philadelphia; Joseph E. Janvrin, M.D., of New York; W. Gill Wylie, M.D., of New York.

A large number of physicians were in attendance and invited to participate in the proceedings.

The annual dues were, on motion, reduced to fifteen dollars per annum.

Resolutions were adopted favoring the formation of a Congress of American Physicians, provided that the arrangement shall not require a surrender of the distinctive title or character of this Society, or interfere

with the full and entire management of its own affairs in every respect.

The Association then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held September 22, 1886, the President, JOHN A. WYETH, M.D., in the chair.

MULTIPLE FRACTURE OF THE PELVIS AND RUPTURE OF THE BLADDER.

Dr. GEORGE F. SHRADY presented the pelvis and bladder removed from the body of an Italian who had been crushed laterally between two moving cars. The patient was brought to the hospital twenty-four hours after the accident, when rupture of the pelvis and extravasation of urine were recognized. Dr. Shrady performed median lithotomy, and on introducing his finger into the bladder found a rupture through the posterior wall on the right. The boggy feel of the pelvic tissues indicated extensive extravasation of urine. The vesical rent was thought to be below the peritoneal line. Suprapubic incision was made, with the intention, should the rupture exist above the peritoneal line, of cleaning out the peritoneal cavity and sewing up the rent. The rent proved to be below the peritoneal line, and through drainage was established. Some loose spiculæ of bone were removed from the pubic arch. The patient did well for twenty-four hours, but finally died on the fifth day after the operation. The post-mortem examination revealed eight fractures at the junction of the pubic and ischiatic bones, and also a fracture through the sacral foramen. The bladder was ruptured on the right and left sides.

CARDIAC HYPERTROPHY—CHRONIC DIFFUSE NEPHRITIS.

Dr. FRANK FERGUSON presented quite fresh specimens illustrating marked capillary injection of the stomach, cardiac hypertrophy, tortuosity, lengthening, and thickening of the arteries at the base of the brain, and advanced diffuse nephritis. The patient's father, mother, and sister had died of cardiac disease. His symptoms were those pertaining to disease of the kidneys and of the heart.

CEREBRO-SPINAL FEVER.

Dr. J. LEWIS SMITH presented the brain of a child, aged 27 months, dead of cerebro-spinal fever. It was an inmate of the Foundling Asylum, and had been tolerably healthy up to three weeks of its death, when it had a convulsion. Three weeks later it had another convulsion; the movements of the left arm became impaired; the rectal temperature was 104° F. There was tonic contraction of the left leg and thigh, but with a little force the limb could be extended. The pupils were moderately dilated, and responded feebly to light. Sight was apparently gone. The *tache cérébrale* was well marked. There was no rigidity of the muscles of the neck. Death took place after three days.

At the base of the brain the pia mater was cloudy, and there were streaks of fibrinous exudation, especially along the fissure of Sylvius, and in this locality were some minute points, not believed, however, to be tubercles. There were no tubercles elsewhere in the body. The pia mater in parts of the cord was injected.

Dr. Smith made the case the basis of some remarks relating to diagnosis of this disease, which he thought was sometimes mistaken for other meningeal affections. Cerebro-spinal fever had become endemic in New York, Philadelphia, Chicago, and other cities throughout the United States. Hence the importance of diagnosis.

ABDOMINAL HÆMATOCELE WITH HEMORRHAGE INTO THE PERITONEAL CAVITY.

Dr. H. N. HEINEMAN presented the specimens, removed from a woman 36 years of age. Three weeks before admission to the hospital she was suddenly seized with cramps in the abdomen, and pains had continued since. A hard mass was felt in the right iliac region, which six days later had increased in size, and the patient was failing, and died the next day. In the abdominal cavity, anterior to and below the promontory of the sacrum, projecting into the pelvis above the brim, was a firm mass, consisting of blood-clot, bound down, but extending above behind the peritoneum. Blood had entered the peritoneum, covering the kidneys, liver, lateral walls of the mesentery, and intestines. There was evidence of abortion.

CEREBRAL APOPLEXY WITH REPEATED HEMORRHAGES.

Dr. HEINEMAN also presented the brain of a man, aged 21 years, who was admitted to Mount Sinai Hospital July 9, 1886. That morning he had suddenly been seized with convulsions and unconsciousness, from which he gradually recovered. He had at times had headache. There were systolic cardiac apex and pulmonic murmurs. The patient was dull, but there was no paralysis. On the 14th the patient left the hospital without any symptom of disease, but weak. Three or four days later he began to complain of frontal headache, pain in both eyes, and vertigo. He had diarrhœa, began to vomit, which continued three days, and he entered the hospital July 30. At this time he seemed rather dull and complained of headache. The pulse was 44, temperature 99.6°. The patient lay quietly in bed until August 8, complaining of headache and being stupid. The left arm and leg were slightly weaker than the right, and the reflexes were diminished upon this

side. There was neuritis descendens. The left pupil reacted more slowly than the right. There was no facial paralysis, nor of the tongue or uvula. The pulse varied from 44 to 56. August 8 the patient became more stupid and irritable; had a slight convulsion. The urine was negative. Four days later he became brighter, and recognized those about him. The slight loss of power on the left side had gradually disappeared. Until September 3 the pulse varied from 56 to 80. On September 3 it rose to 87. The next day the patient seemed to fail; the pulse 120, temperature 100.5° F. During the last three weeks the patient lay in a semi-stupor, delirious at night; but there was no paresis. September 8 there was a chill; temperature 104.6°, pulse 144; symptoms of cystitis; a convulsion; opisthotonos, patient restless, pupils slightly dilated; conjunctiva slightly sensitive; râles over both lungs; systolic basic murmur. The patient remained stupid four days, when he again brightened and was able to eat alone in bed. September 15 his pulse, which had become depressed, again rose to 102; the temperature rose to 102° F. He again became stupid, but rallied again September 18, when he could with effort be made to answer. He died suddenly September 19.

The calvaria was thin; the pia mater was dull, with considerable serum beneath at the base; the convolutions appeared flat. In the left frontal lobe, above the gyrus fornicatus, was an ovoid mass covered with white brain-substance, projecting to the right of the median line. The mass was one and one-half inches by two inches in its diameters, egg-shaped, and consisted of a clot, partly recent, but principally of some duration, and quite firm, The surrounding brain-substance, extending to the roof of the left lateral ventricle, but not involving the cortex, was undergoing yellow degeneration. The lateral ventricles contained only a slightly-increased amount of serum; the heart was normal; the bladder showed acute inflammation; both kidneys were swollen and congested; the aorta was narrow and its walls thin.

Dr. Heineman called attention to the fact that several cases were now on record in which young men dead of cerebral apoplexy had been found at post mortem to have an abnormally small aorta. He referred to a case of the kind presented to the Society by Dr. Peabody.

Dr. FRANK FERGUSON had seen four specimens removed from the bodies of young men who had died of cerebral apoplexy and in whom the aorta was found to be unusually small.

ARTIFICIAL QUININE BY SYNTHESIS.—Mr. Cresswell Hewett, of England, claims to have successfully solved the problem of making quinine from a common article everywhere present, so that it can be sold at about six cents per ounce.

REVIEWS AND BOOK NOTICES.

TRANSACTIONS OF THE AMERICAN GYNÆCOLOGICAL SOCIETY. Vol. X. For the Year 1885. New York. 8vo, pp. 357.

In this handsomely-printed volume appear the President's Address and the communications made at the Washington meeting. Two rare cases in abdominal surgery illustrating the difficulties in diagnosis in some cases were the subject of the address of the President, by Dr. William T. Howard, of Baltimore. The first was a case of encysted effusion, with tubercular peritonitis simulating uterine fibro-myoma, the fluid from which coagulated spontaneously; the second was a case of suppurative peritonitis, also tubercular, simulating ruptured ovarian cyst. The address and the subsequent discussion were devoted principally to questions of diagnosis and the justifiability of exploratory operation.

Dr. Samuel C. Busey, of Washington, in a paper on the Natural Hygiene of Child-Bearing Life, calls attention to some prevalent dangers to health among women. Puerperal Diphtheria is the title of a paper contributed by Dr. Henry J. Garrigues, of New York, based upon cases occurring in his hospital practice. Irrigation of bichloride solution (1 to 2000) and suppositories of iodoform (iodoform, ʒx, amylum and glycerin, ʒj, pulv. acaciæ, ʒij, to make six suppositories for introduction into the uterus). When the patches are spreading, a solution of chloride of zinc is applied on a swab. Besides the local treatment, he gives fluid extract of ergot, morphia, quinine, alcoholic stimulants, and tincture of digitalis. Carbolic acid in one-minim doses every hour is good both as an antiseptic and to combat diarrhœa. Where danger of infection exists, an antiseptic pad is directed to be worn, wrung out of the corrosive-sublimate solution.

Dr. Joseph Taber Johnson reports four cases of oöphorectomy, with remarks, which led to an extended discussion.

Protection of the Peritoneum during Parturition is the subject of an able contribution by Dr. Thad. A. Reamy, of Cincinnati.

Dr. Edward W. Jenks, of Detroit, reports a Case of Cæsarean Operation, with some comments, in a patient who had previously been delivered of a living child, but had subsequently suffered a fracture of the pelvis.

Dr. Ellwood Wilson contributes some Remarks on the Use of Tarnier's Forceps, in which he renounces his previous condemnation of this instrument. He prefers Howard's modification. They are to be used for all applications at the superior strait or high up in the pelvis.

Dr. R. Stansbury Sutton has a paper describing A Modification of Emmet's Cervix Operation in Certain Cases.

Inflammation of the Parotid Glands follow-

ing Operations on the Female Genital Organs is the title of a paper by Dr. William Goodell, of Philadelphia.

The remaining papers are "Peristalsis of the Genital Tract and a New Theory to Explain Relaxation of the Vaginal Outlet," by James R. Chadwick, M.D.; "Facial Paralysis in the New-Born caused by the Forceps," by Theophilus Parvin, M.D.; "The Genu-Pectoral Posture in the Prolonged Nausea and Vomiting of Pregnancy, with Cases," by Henry F. Campbell, M.D.; "Mural Abscesses following Laparotomy," by James B. Hunter, M.D.; "Pelvic Abscess," by William H. Parish, M.D.; and "Laparo-Elytrotomy," by Charles Jewett, M.D.

The papers are, as a rule, decidedly valuable contributions, while the discussions elucidate the subjects considered and illustrate many of the difficulties in diagnosis and uncertainties in practice that are inseparable from a science in a state of progress.

NEW REMEDIES AND CLINICAL NOTES.

Treatment of Stricture of the Urethra by Electrolysis.—Dr. Robert Newman, of New York, in a communication to the *Medical Record*, gives the following instruction with regard to this valuable method of treatment:

1. Any good galvanic battery will do which has small elements and is steady: the twenty-cell Drescher battery, carbon and zinc, is an excellent instrument, sufficient particularly for the beginner.

2. The fluid for the battery ought not to be used too strong.

3. Auxiliary instruments, as galvanometer, etc., are important to the expert, but are not necessary for the beginner.

4. For the positive pole a carbon electrode is used, covered with sponge moistened with hot water, and held firmly against the cutaneous surface of the patient's hand, thigh, or abdomen.

5. For the absorption of the stricture the *negative* pole must be used.

6. Electrode-bougies are firm sounds insulated with a hard-baked mass of rubber; the point is a metal bulb, egg-shaped, which is the acting part in contact with the stricture.

7. The curve of the bougie is short: large curves are mistakes.

8. The plates must be immersed in the fluid before the electrodes are placed on the patient, and raised again after the electrodes have been removed.

9. All operations must begin and end while the battery is at zero, increasing and decreasing the current slowly and gradually by one cell at a time, avoiding any shock to the patient.

10. Before operating, the susceptibility of the patient to the electric current should be ascertained.

11. The problem is to absorb the stricture, not to cauterize, burn, or destroy tissues.

12. *Weak currents at long intervals.*

13. In most cases a current of six cells, or from two and a half to five milliampères, will do the work; but it must be regulated according to the work to be done.

14. The séance should be at intervals not too frequent in succession.

15. The best position for the patient to assume during the operation is that which is most comfortable for himself and the operator. I prefer the erect posture, but the recumbent or others may be used.

16. Anæsthetics I like to avoid: I want the patient conscious, so that he can tell how he feels.

17. Force should never be used; the bougie must be guided in the most gentle way; the electricity alone must be allowed to do the work.

18. During one séance, two electrodes in succession should never be used.

19. All strictures are amenable to the treatment by electrolysis.

20. Pain should never be inflicted by the use of electrolysis: therefore it should not be applied when the urethra is in an acute or even subacute inflammatory condition.

Animal Vaccine.—Dr. Charles R. Drysdale read a paper at the meeting of the British Medical Association on "The Superiority of Animal Vaccine." In 1877 he had studied animal vaccination in Brussels, at Dr. Warlomont's institution, and then had recommended in the Medical Society of London that calf-lymph should take the place of long-humanized lymph, for three reasons: 1, because in times of epidemics of smallpox calf-lymph could be had in quite unlimited quantities; 2, because it could not be accused of conveying syphilis; and, 3, and by far the most important of all, because evidence showed that animal vaccination was considerably more protective against smallpox than long-humanized lymph. This latter was proved by the remark of Dr. Warlomont that, in the terribly severe epidemic of smallpox of 1870–71, no person who had been vaccinated with animal lymph took the disease, and by the evidence given by Dr. Martin, the great vaccinator of the United States, recently deceased, that he had offered a reward of one hundred pounds to any one who should show him a case of smallpox which had occurred in a patient vaccinated by him with animal vaccine, and that no one had been able to claim the reward offered. Mr. Babcock, a chemist of Brighton, had clearly shown, by inoculating some two hundred cows with smallpox matter and obtaining a vaccine vesicle in thirty-three cases, that smallpox and vaccine were the

same disease, and that when we vaccinated ourselves we merely took a mild attack of smallpox. At the beginning of the century, when the illustrious Jenner was alive, human lymph was more preventive than now, because nearer to animal vaccine, and we should, therefore, as had been done in the United States, abandon the use of humanized arm-to-arm vaccination, and have recourse solely to calf-lymph for vaccination.—*Medical Record.*

A New Cause of Presystolic Murmur.—At the meeting of the Medical Section of the Academy of Medicine in Ireland, Dr. Finny called attention to an additional cause of presystolic murmur which had recently come under his own observation, and no other example of which he had yet found. In Sir Patrick Dun's Hospital there was a case of simple hypertrophy of the left ventricle from cirrhosis of the kidney. Subsequently dilatation of the cavity had taken place, and there was the systolic sound of mitral regurgitation of a functional nature,—a case of weakening muscle already in a state of hypertrophy. During the last ten days of the patient's life in hospital a new murmur developed,—namely, a presystolic murmur. He could not then explain it; but after death, which ensued on epileptic convulsions of the uræmic type, he discovered the cause. Looking at the heart, there was hypertrophy of the left ventricle, with some dilatation; but all around the mitral curtains there was a large mass of fibrin deposited as large as a filbert, especially behind the ventricular aspect of the posterior valve. He believed that to be the true explanation of the presystolic murmur during the last ten days. Embolism was recognized during life, due doubtless to this thrombus, and there was an enormous obstruction of the spleen, the largest he ever saw; but he was not prepared to find so large a quantity of ante-mortem clot existing in that condition, nor was he aware that such a condition could produce such a narrowing of the orifice as to produce a presystolic murmur.—*Dublin Journal of Medical Science.*

Microbes as Factors in the Formation of Foreign Bodies and Calculi.—At the Paris Biological Society, M. Galippe stated that he had examined arthrophytes removed from a knee, and had observed microbes in them the same as he had detected in calculi removed from the bladder; he had isolated them and cultivated them. This investigator is therefore confirmed in his belief that the crystallizations found in the human economy develop through the agency of microbes; then microbes are pathogenic parasites of the foreign bodies of the animal economy, whatever may be the chemical composition of these bodies and wherever they may be found.—*New Orleans Med. and Surg. Journal.*

MISCELLANY.

The private hospital of Dr. William H. Pancoast, conveniently located at 1006 Walnut Street, Philadelphia, is now open for the reception of surgical patients. The experience of the first year of this institution has proved its usefulness. It is fitted up with the modern conveniences, with baths, Flemming's electrical cabinet, etc., and has a resident physician and trained nurses always in attendance.

Drs. Warder and Montgomery have formally opened their new private operating hospital, located at 1601 Master Street. It is complete in its appointments for the treatment of gynæcological cases.

J. William White, M.D., has been elected Professor of Genito-Urinary Diseases in the Medical Department of the University of Pennsylvania.

Dr. William H. Greene has removed to 204 North Thirty-Sixth Street, Philadelphia.

Dr. S. D. Risley has removed to 1722 Walnut Street.

Dr. Addinell Hewson, Jr., has removed to 1816 Spruce Street, Philadelphia.

NOTES AND QUERIES.

A CASE OF STRYCHNINE-POISONING.

Dear Sir,—I report the following case of strychnine-poisoning merely to place it upon record.

September 26, 1884, about 7 P.M., I was hurriedly called to see E. N. G., a large, robust man, age 42, weight about two hundred pounds, who had in a condition of semi-intoxication "taken a teaspoonful of strychnine." I reached the patient one hour after the ingestion of the poison, found him suffering terribly with intense muscular rigidity, especially about the cervical, dorsal, lumbar, and sacral regions, and well-marked muscular twitching about the face, arms, and legs. No convulsions or loss of consciousness. His wife exhibited to me a one-ounce strychnine-vial one-third full of sulphate of strychnine, saying she had used not above one-third of the original amount contained in the vial for the purpose of destroying rats, and her husband had taken the rest by pouring it into a teaspoon and dissolving it in half a glass of water: which would be one-third of the original contents of the vial, or twenty grains.

Treatment, thirty grains of sulphate of zinc and one drachm of fluid extract ipecac in a teacupful of warm water, which acted promptly as an emetic. In twenty minutes the same dose was repeated, again acting thoroughly. I then gave sixty grains of bromide of potassium and thirty grains of hydrate of chloral, and repeated this dose in one hour. Two hours following, half the dose; and the next two hours, half the dose. Thus in about five hours he had taken one hundred and eighty grains of bromide and ninety grains of chloral. Further treatment was then discontinued, as patient was in a quiet sleep and muscular relaxation rapidly going on.

Called to see him the following morning at nine o'clock. Found him in the yard, splitting wood. No further unfavorable symptoms. Very respectfully,

D. DUNKLIN.

Bonne Terre, Missouri, October 4, 1886.

CALOMEL TREATMENT OF CROUP.

MR. EDITOR,—I notice in the report of the proceedings of the Eighth Annual Session of the American Laryngological Society that Dr. William H. Daly, of Pittsburg, notices the calomel-treatment of croup. He appears to consider croup and diphtheria as one and the same, and would seem to make calomel the best medicine for all kinds of croup.

In this, after considerable experience, I differ from him. For more than thirty years I have treated inflammatory croup with small doses of calomel repeated every hour, and found it the most successful practice. I have sought its alterative effects, and have restrained by a very little opium its action on the bowels, deprecating whatever debilitates. But a few dark, bilious stools are not hurtful, but rather a good omen. However, the strength of the child must be husbanded till the cough gradually softens, the breathing improves, and the voice returns.

But I do not think the calomel should be relied on alone. The important adjunct of steam should never be dispensed with, and an occasional emetic of turpeth mineral and ipecac in the very early stage is of much benefit.

I have tried the calomel-treatment in several cases of diphtheritic croup, but have not as yet seen any benefit from its use. Diphtheria seems too asthenic in its nature for the use of mercury.

The old American physicians appear to have become acquainted with the benefits of calomel in croup before Dr. Hamilton and others in Europe. See Stillé's "Therapeutics," vol. ii. p. 714.

I think Dr. Daly has done well to call attention to this important remedy in a disease that so often baffles the best skill of the best men. ALEX. W. ROGERS.

PATERSON, NEW JERSEY, September 30, 1886.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 26, 1886, TO OCTOBER 9, 1886.

MAJOR DALLAS BACHE, SURGEON.—Granted leave of absence for twenty-five days, to take effect on or about October 2, 1886. S. O. 143, Division of the Atlantic, September 24, 1886.

MAJOR JOSEPH R. GIBSON, SURGEON.—Granted two months' leave of absence from September 25, 1886, on surgeon's certificate of disability, in lieu of the unexpired portion of the ordinary leave of absence granted him in S. O. 158, A. G. O., July 10, 1886. S. O. 227, A. G. O., September 30, 1886.

MAJOR WILLIAM H. GARDNER, SURGEON.—Ordered from Department of Texas to Department of the East. S. O. 227, A. G. O., September 30, 1886.

CAPTAIN WASHINGTON MATTHEWS, ASSISTANT-SURGEON.—Granted leave of absence for one month and twelve days, with permission to go beyond sea. S. O. 232, A. G. O., October 6, 1886.

CAPTAIN DANIEL M. APPEL, ASSISTANT-SURGEON.—Assigned to duty at Fort Davis, Texas. S. O. 133, Department of Texas, September 22, 1886.

FIRST-LIEUTENANT W. W. R. FISHER, ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 230, A. G. O., October 4, 1886.

FIRST-LIEUTENANT WILLIAM C. BORDEN, ASSISTANT-SURGEON.—Relieved from temporary duty at Fort Bridger, Wyoming, and ordered to return to his station, Fort Douglas, Utah. S. O. 126, Department of the Platte, October 2, 1886.

FIRST-LIEUTENANT PHILIP G. WALES, ASSISTANT-SURGEON.—Leave of absence extended to include November 5, 1886. S. O. 226, A. G. O., September 29, 1886.

FIRST-LIEUTENANT WILLIAM P. KENDALL, ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 81, Division of the Pacific, September 24, 1886.

FIRST-LIEUTENANT CHARLES F. MASON, ASSISTANT-SURGEON.—Ordered for temporary duty at Fort Verde, Arizona Territory. S. O. 90, Department of Arizona, September 20, 1886.

COLONEL JOHN F. HAMMOND, U. S. ARMY (Retired).—Died at Poughkeepsie, New York, September 29, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FROM SEPTEMBER 12, 1886, TO OCTOBER 9, 1886.

PASSED ASSISTANT-SURGEON M. H. SIMONS, PASSED ASSISTANT-SURGEON E. NORFLEET.—Detached from the "Alert" and placed on waiting orders.

MEDICAL-INSPECTOR E. S. BOGERT.—Ordered to Navy-Yard, New York, September 28, 1886.

PASSED ASSISTANT-SURGEON D. M. GUITERAS.—To Receiving-Ship "Franklin" for temporary duty, October 3, 1886.

ASSISTANT-SURGEON A. R. WENTWORTH.—Detached from Navy-Yard, League Island, and to the U.S.S. "Galena," October 1, 1886.

ASSISTANT-SURGEON H. B. SCOTT.—Ordered to Navy-Yard, New York, October 1, 1886.

PASSED ASSISTANT-SURGEON RICHARD ASHBRIDGE.—Detached from the U.S.S. "Sahara" October 1, 1886, and granted six months' leave.

ASSISTANT-SURGEON T. A. BERRYHILL.—Detached from the Museum of Hygiene and ordered to Receiving-Ship "Minnesota."

PASSED ASSISTANT-SURGEON GEORGE ARTHUR.—Detached from the Navy-Yard, New York, and ordered to the Museum of Hygiene.

PASSED ASSISTANT-SURGEON H. T. PERCY.—Detached from the U.S.S. "Galena," proceed home, and wait orders.

ASSISTANT-SURGEON JOSEPH SHAFER.—Detached from the U.S.S. "Minnesota," and ordered to the U.S.S. "Swatara."

PASSED ASSISTANT-SURGEON J. M. STEELE.—Detached from Naval Academy and granted six months' leave.

PASSED ASSISTANT-SURGEON CLEMENT BIDDLE.—Ordered to Naval Academy, Annapolis, Maryland.

MEDICAL-DIRECTOR JAMES SUDDARDS.—Will convene Medical Board October 6, 1886.

MEDICAL-DIRECTOR J. MILLS BROWNE.—Ordered to report to President of Medical Board October 6, 1886.

MEDICAL-DIRECTOR R. C. DEAN.—Ordered to report to President of Medical Board October 6, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED OCTOBER 9, 1886.

PURVIANCE, GEORGE, SURGEON.—Granted leave of absence for twenty-five days, September 30, 1886.

STONER, G. W., SURGEON.—Granted leave of absence for twenty-three days, October 1, 1886.

CARTER, H. R., PASSED ASSISTANT-SURGEON.—To proceed to Galveston, Texas, as inspector, September 30, 1886.

AMES, R. P. M., PASSED ASSISTANT-SURGEON.—Granted leave of absence for thirty days, to take effect when relieved, September 30, 1886.

WASDIN, EUGENE, ASSISTANT-SURGEON.—Ordered to examination for promotion, September 30, 1886.

BROOKS, S. D., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, to take effect when relieved, September 30, 1886.

WILLIAMS, L. L., ASSISTANT-SURGEON.—Relieved from duty at Mobile, Alabama; ordered to Marine Hospital, Wilmington, North Carolina, September 27, 1886.

PERRY, T. B., ASSISTANT-SURGEON.—Relieved from duty at San Francisco, California; ordered to Marine Hospital, St. Louis, Missouri, October 1, 1886.

PECKHAM, C. T., PASSED ASSISTANT-SURGEON.—Granted leave of absence for thirty days, to take effect when relieved, October 5, 1886.

KALLOCH, P. C., PASSED ASSISTANT-SURGEON.—Granted leave of absence for twenty-one days, to take effect when relieved, October 5, 1886.

PETTUS, W. J., ASSISTANT-SURGEON.—To proceed to Evansville, Indiana, for temporary duty, October 8, 1886.

KINYOUN, J. J., ASSISTANT-SURGEON.—Appointed an Assistant-Surgeon October 4, 1886; assigned to temporary duty at New York, October 5, 1886.

PHILADELPHIA, OCTOBER 30, 1886.

ORIGINAL LECTURES.

ON PSORIASIS.

BY HENRY J. REYNOLDS, M.D.,

Professor of Dermatology in the College of Physicians and Surgeons, Chicago, Illinois; Professor of Skin and Genito-Urinary Diseases, Chicago Polyclinic.

Reported by WILLIAM WHITFORD.

GENTLEMEN,—This little girl, 10 years of age, comes to us to-day with a history of having had an eruption upon her body continuously for four years. Before investigating the case, however, let me enumerate some of the more important characteristics of the disease known as "psoriasis," of which this is a rather well marked case. It is not a contagious disease; it appears at any age, and in both sexes. It will occur in those of the most robust constitution as well as the delicate. The eruption always has a tendency to general or symmetrical distribution,—that is, we are liable to find an eruption on any part of the body, or, more correctly speaking, we find it upon all parts of the body at the same time. The eruption may be comparatively scarce in certain localities, though we find some patches all over the body. For instance, we find some patches on the scalp, on the extremities, and on the trunk. The disease has a tendency to chronicity, lasting in some instances for many years. The case before us has existed for four years. The lesions in the disease—by that I mean the diseased patches—are almost always round, at least they have that tendency, and vary in size from a pin-head to a silver dollar, although they usually average from the size of a ten-cent piece to about a quarter of a dollar, as in the plate I now show you. This plate represents a case of psoriasis, and thus gives you an idea as to the size of the lesion. I may next mention one of the most important characteristics of the disease,—viz., the scales covering the patches: they are always white, shining, silvery scales. The skin between each one of these little patches is always healthy,—that is, the disease terminates abruptly at the margin of the patch; it does not extend beyond the patch, as in certain other diseases. Now, when these white, shining, silvery scales are removed we find a red patch underneath; and upon a little closer examination we find some pin-point oozing of blood. There is no more important symptom in psoriasis than the one I have just alluded to (these pin-point-size droplets of blood). I may mention further with regard to the scales, that at first sight or examination we do not always find or observe their white, shining, silvery character, but by gently rubbing the patches with the finger-nail this character is clear at a glance. Another very important characteristic of the disease is that it is dry from first to last; we never have any history of moisture, as in certain other diseases of the skin. This is an important point to remember, because by knowing all the characteristics of the disease it will be impossible for you to fail in making a correct diagnosis, and there is no other way to make a diagnosis than by remembering these points. We have very few subjective symptoms in this disease: by this I mean we have very few symptoms which are manifested by the feelings of the patient, such as itching, pain, or similar sensations. This feature is so marked that the patient might have an eruption on the back or some other region and not know it, merely because there is no itching sensation, or at least comparatively none when compared with some other diseases. For this reason it is always well to examine the entire body, because the patch exhibited to you might only be the simplest indication or portion of the actual disease. The patient may have the eruption all over the body and not know it. Another very important feature is that, although it has a tendency to general distribution, it prefers certain localities of the body. The localities it favors are the extensor surfaces, such as the knees and elbows, etc. The eruption does not always remain in the same outline, but it may take on certain other shapes; the lesions may run together into one conglomerated mass, hence various names have been given to indicate the different appearances of the disease. For instance, when the eruption is very fine it is called psoriasis punctata; when a little larger in size, psoriasis guttata; when it is still larger in size, as we usually find it, it is termed psoriasis nummularis, or round, coin-size patches; and when many of these lesions all run together in one mass, it is designated psoriasis diffusa. You will re-

member that I said this disease is a symmetrical or generalized one, and that it prefers certain localities. I will mention two localities where it almost never occurs, and these are upon the palms of the hands and soles of the feet. We may say it must be rare that an uncomplicated case of psoriasis affects the palms and soles.

Now, all the symptoms I have just alluded to are not always present in every case of this disease, otherwise we would never have any trouble in making a diagnosis. We find present, however, in the case of this little girl many of the characteristics previously referred to.

It is evident from her having had it for four years that it is a very chronic disease. She gives us no history of contagion. You will notice there is a tendency to rotundity of the lesion, and that the lesions have a well-defined contour. By carefully scratching the surfaces of these scales with your finger-nails you will find they assume the white, shiny character. By removing some of the scales you will find the red, bleeding patch underneath. You must scratch it closely in order to get down to the bottom, and then you will find the characteristic pin-point-size droplets of blood, which characteristic of itself alone is almost pathognomonic. That, in addition to the white, shiny character of the scales, will enable you to almost make a good diagnosis, but it is never a good rule to follow: always sum up the diagnostic points. You will observe we have no moisture whatever. The lesions everywhere you see them are the same; we find no papules, pustules, vesicles, or anything of that kind.

Now, these characteristics are indicative of psoriasis, although you may meet with some of them in certain other skin-diseases; and it is therefore well to make a differential diagnosis, knowing that many of the symptoms found here appear in other affections of the skin. The diseases that resemble, to the greatest extent, psoriasis, are eczema, syphilitic eruption, favus, seborrhœa, and tinea tonsurans.

In psoriasis as distinguished from eczema we have no subjective sensations, while in eczema we have great itching. In psoriasis the disease is dry from first to last, while in eczema we have a history of moisture; psoriasis prefers the extensor surfaces, eczema the flexor. The patches in psoriasis are well defined, while in eczema they gradually fade away. The scales in psoriasis are white and shiny, while in eczema we may have crusts instead of scales. We have red, bleeding patches in psoriasis which we do not have in eczema. Again, eczema is to a certain extent local, while psoriasis has a tendency to general distribution. Another important differential diagnostic point is that in psoriasis, while the patches may be thick on the scalp and fringe the brow, they spare the face; the face, on the other hand, is a favorite locality for eczema. The palms and soles are very rarely involved in psoriasis, while these parts are very commonly affected by eczema. In psoriasis the skin is healthy between the lesions, while in eczema such is not the case. The lesions in psoriasis are never different in any respect from those you see in this well-marked typical case, while in eczema we may have all forms of lesion, as vesicles, papules, pustules, etc.

Psoriasis as distinguished from Syphilitic Eruptions. — We have, first, the white, shining scales; in syphilis the scales are not so shiny and white, and we may have crusts instead of scales in syphilis. The scales are loose in psoriasis, while in syphilis they are more adherent. The patch in psoriasis is always as you observe it in this case, covered completely with scales; there is not a particle of the red patch to be seen; while in syphilitic eruptions the scales are fewer and do not cover the entire patch. Here we have a syphilitic eruption; but it has not advanced to that stage where it might be mistaken for psoriasis, because the scales have not accumulated. When they do accumulate, they never cover the entire patch; the margin of the patch may be seen in its red condition. The patch in psoriasis is a bright red, while in syphilitic eruptions it is a copper color or dark red; no inflammatory color about it. We have the pin-point bleeding in psoriasis when the scales are removed, to which I have previously referred, that we do not have in syphilis. Again, as regards the lesions, we apply the same contrast as between eczema and psoriasis: viz., in psoriasis they are uniformly the same, while in syphilitic eruptions we may have many forms of lesions. It is true when the lesions first appear in syphilis they resemble those of psoriasis; but in a few months they change their character and go on to pustulation, ulceration, and destruction of the skin. The

palms and soles are nearly always affected in syphilis, and almost never in psoriasis. We have the dry character in psoriasis, while in syphilis we may have various forms of moisture, such as the formation of pus, exudation of serum, etc. Psoriasis is never a destructive disease, while syphilis always, sooner or later, results in destruction of the tissues.

A differential diagnosis between psoriasis and syphilis would hardly be necessary if syphilitic patients were always able to give a syphilitic history; but sometimes this is not the case. In the case before us, however, it would not be necessary to make a differential diagnosis between psoriasis and syphilis, for the reason that the disease has existed four years and has always remained continuously and uniformly the same; whereas in syphilis such a thing would be impossible. The lesions are well formed in syphilis, and in a few months change from one form into another. We have pustulation, ulceration, and destruction within a very brief period.

Where psoriasis is mostly confined to the scalp we have to differentiate it from certain other diseases of the scalp, such as favus, tinea tonsurans, and seborrhœa.

Favus may be at once excluded by the yellow color of the crust, by the brittle, broken-off condition of the hairs, and by their falling or pulling out readily. Favus is a disease confined almost invariably to the scalp. Further, there is this difference between the two: favus never extends down and fringes the brow as in this case, a condition which is very common in psoriasis.

Now, with regard to tinea tonsurans or ringworm of the scalp, we have a brittle, broken-off condition of the hairs; the disease is not uniformly and symmetrically spread over the scalp as psoriasis is. Besides, this disease and favus being parasitic diseases, we have the history of contagion and the discovery of the parasite with the microscope.

As regards seborrhœa, that is simply a disease of the sebaceous glands, a disease diffusely spread over the scalp; doesn't spare a particle of it: in other words, we do not have the character of healthy skin between the lesions. It affects the scalp diffusely, not in elevated patches, but is uniformly and diffusely spread all over it; it never extends down over the brow to the non-hairy portions. The scales are greasy in character; sometimes there is considerable loosening of the hair, a condition we never meet with in psoriasis of the scalp.

As regards treatment, I always think when we have made our diagnosis that most of our work is done. It may be very difficult to *cure* a disease in some cases, but it is not a difficult matter to apply the remedies laid down in the text-books: this is a very simple matter when you know what the disease is. Now, in this disease, occurring as it does in the most robust as well as the delicate, constitutional measures have but very little effect. The treatment, therefore, must be mainly local. Certain remedies, however, are given sometimes internally: for instance, arsenic given in the form of Fowler's solution. I mention this remedy because it is recommended in the text-books by various authors, rather than because I think it advisable and useful myself, for I rarely use it. You may give it in ordinary doses, five to ten drops three times a day.

As regards local treatment, I may mention first the use of *chrysarobin*, and, second, *pyrogallic acid* and various mercurial ointments. I would like you to bear in mind, however, the chrysarobin for the treatment of psoriasis, because I consider it the best. It is a specific local remedy; but before applying it let me mention some preliminary measures. With these scales covering the patch almost impermeably, it would be useless to apply any specific medication on top of them: it would not penetrate to do any good. The first thing to be done is to remove the scales. This applies to almost every skin-disease. How shall we do this? The best means of doing it, I think, is as follows. Oil the parts twice a day with any oleaginous preparation, some penetrating oily substance being preferable. I might state that vaseline is not good for this purpose: it is not a pure fat; it is gummy and resinous, and does not penetrate well. Olive-oil, or the new remedy talked of, called *lanoline*,—in fact, any oleaginous preparation to loosen and soften these scales,—may be applied twice a day; then at night a hot bath, with plenty of soap, and a good brush or rough towel to take off the scales. The next day repeat the same process, and by the second night you may have most of the scales off. Apply then the chrysarobin, twenty grains to the ounce of some inert fat or ointment;

it may be mixed with vaseline, but pure lard is better; rub it twice or three times a day. Every patch requires its individual treatment.

These scales have a tendency to re-accumulate, and in the course of a few days it will be necessary to repeat the other treatment: that is, the oiling and washing of the parts. Then again go on with your specific medication in the form of chrysarobin-ointment as before, and thus keep the process going on alternating until the lesions have dried down and the scales are not reproduced, which is sure to take place in due time. The pyrogallic acid may be used in the proportion of a drachm to the ounce, first getting rid of the scales, as previously stated.

As regards the prognosis: the disease is a chronic one. It can always be readily cured by being very thorough. This is to a certain extent beyond the control of the physician, however, because the patient or attendants have to do most of the work,—the rubbing and washing, etc.,—and if this is not thoroughly carried out you will fail in getting a speedy cure. Once the disease is cured or healed, it is all right for a time; but, without good care of the skin, it is liable to return again. This is an important feature in the prognosis, and its liability seems to be greater in cold than warm weather. Measures which tend to keep the skin active are indicated with a view to preventing a return of the disease.

ORIGINAL COMMUNICATIONS.

A CONSIDERATION OF THE BACTERIA OF SURGICAL DISEASES.

Read, by invitation, before the American Surgical Association

BY HAROLD C. ERNST, A.M., M.D. HARV.,

Demonstrator of Bacteriology in the Medical School of Harvard University.

(Continued from page 48.)

INOCULATION experiments have been made in considerable number to test the pathogenic powers of the various organisms which I have had under observation. Here, again, the method employed has been that of Koch. The place selected for the inoculation has been first thoroughly cleansed and then soaked in a solution of corrosive sublimate (one to one thousand), the hands of the operator have been sterilized with the same solution, and for inoculation a syringe like the one I have here has always been employed. It may be readily taken apart and cleansed, has no packing or other parts to become foul, and may be subjected to any temperature required for sterilization. In all cases these syringes have been subjected to 150° C. for an hour just before being used. The material for inoculation has been prepared in the case of cultures in gelatin media by simply melting the gelatin, pouring it into a sterilized capsule, and then using the required quantity in the syringe shown; or, when the cultures were upon nutrient agar-agar, by placing a portion of the culture in boiled distilled water and using this in the same way as the liquefied gelatin cultures.

The animals used were all selected for their apparent condition of good health, had all been under observation for some time before the operations, many of them having been kept in the country miles away from other animals, and were all kept under the very best possible hygienic conditions. The result of these precautions is seen in the fact that in no single case did the post-mortem examination reveal any abnormal condition of affairs that might not fairly be attributed to the activity of the bacteria which had been injected.

The animals employed were guinea-pigs. Mice were excluded because symptoms produced in them are not fairly comparable to those obtained in larger animals, and rabbits could not be obtained in Boston at any price during the time that I was carrying on my inoculation experiments.

The bacteria with which I have experimented are the following:

The Staphylococcus aureus and albus.
The Staphylococcus pyogenes citreus.
The Erysipelas coccus.
The Streptococcus cereus flavus.
The Streptococcus pyogenes.
The Micrococcus pyogenes tenuis.
The Bacillus pyogenes fluorescens.

The records of the inoculation experiments are as follows:

Inoculation experiments with the Staphylococcus pyogenes aureus.

I. A full-grown healthy guinea-pig inoculated in a vein of one leg made prominent by partial constriction. Two drops of a pure culture in gelatin of the sixteenth

generation of the Staphylococcus aureus from the first case reported (ununited fracture of the arm) were employed. The cultivations had been conducted out of the body for over a year. Death occurred in less than twelve hours. The autopsy showed very little change in the internal organs: the heart was much distended and full of fluid blood. Cover-glass preparations showed the blood to contain numerous micrococci, and cultivations made from the blood in nutrient gelatin showed the presence of the Staphylococcus aureus.

II. An adult guinea-pig inoculated with the same culture as the preceding, under the skin of the abdomen, two cubic centimetres of the cultivation in gelatin being used. Killed in ten days. An abscess the size of a marble, filled with thick yellowish pus, was found just under the point of inoculation. Cover-glass preparations of this pus and sections of the abscess-wall showed the presence of large numbers of micrococci. Cultivations were made in gelatin and upon agar-agar (37° C.) from the abscess, from the blood, and from the peritoneum. Very free growth of the Staphylococcus aureus was obtained from the first, but neither the cultivations nor cover-glass preparations from the blood or peritoneal cavity showed the presence of any bacteria whatever.

III. A guinea-pig inoculated with the same amount and material as the preceding, except that the inoculating needle was plunged deep into the abdominal cavity. Dead in ten hours. Examination showed only a marked redness about the point of inoculation, and that the needle had not penetrated the intestines. The heart was much distended with fluid blood. Cultivations were made from the point of inoculation, the peritoneal cavity, and the blood of the heart, and liver, and spleen, in gelatin and agar-agar. No growth appeared in any of the tubes except those sown from blood, and this growth proved to be the Staphylococcus aureus.

The contrast between the results of the last two experiments is very marked,—in the first case the organisms being found only in the abscess and not in the blood, and in the second case being only in the blood and not about the point of inoculation. In the first case the effect was purely local, and in the second it was general and of a septicæmic character.

IV. Staphylococcus pyogenes aureus from a perinephritic abscess (Case II.), seventeenth generation, cultivated for over a year. Two cubic centimetres of nutrient gelatin containing a culture were injected under the skin of the back of a guinea-pig. Killed in four days. An abscess about an inch long by one-half inch broad, and three lines in thickness, full of thin yellow pus, was found just beneath the skin. Cultivations made from this showed the presence of the Staphylococcus aureus, and microscopic examination showed masses of micrococci in the pus and in the abscess-wall. Cultures from the blood gave no result whatever.

V. The same amount and material were employed as in the preceding experiment, and the inoculation was made subcutaneously over the abdomen. In two days death occurred. Section showed a very marked congestion of all of the abdominal viscera, with an abscess about one-half inch in diameter at the point of inoculation. Cover-glass preparations of the pus and sections of the abdominal wall showed the presence of masses of micrococci, whilst cultivations in nutrient gelatin and on agar-agar gave abundant growth of the Staphylococcus aureus. Cultures of the same organism were also obtained from the blood, and cover-glass preparations of the blood showed it to contain a number of micrococci.

VI. Staphylococcus aureus from a perinephritic abscess (Case IV.), eighteenth generation, cultivation extending over eight months. Two cubic centimetres of a culture in nutrient gelatin were injected into the abdominal cavity of a healthy guinea-pig. Killed on the fourth day. The animal was moribund. Section showed the presence of an extensive purulent peritonitis, and microscopic examination of the pus together with cultivations made from it demonstrated the presence of the Staphylococcus aureus. Cultures from the blood and microscopic examination of the same revealed absolutely nothing abnormal; no bacteria were found.

VII. Staphylococcus aureus. The same experiment as the preceding was performed in the same way, and with the same result, except that the animal was killed on the second day. The inflammatory process with the suppuration seemed to be, if anything, more extensive. The same results were obtained by microscopic and cultivation experiments; the Staphy-

lococcus aureus was found in the pus but not in the blood.

VIII. Staphylococcus aureus from a psoas abscess (Case XIV.), the twelfth generation, cultivation out of the body extending over seven months. Four cubic centimetres of a solution in distilled water of one drop of a pure culture in nutrient gelatin were injected into the abdomen of a healthy guinea-pig. In two days a swelling the size of an English walnut could be felt under the point of inoculation. Killed at the end of twelve days. The remains of an abscess were found, the cavity having almost closed; only a few drops of thick yellowish pus were obtained. Microscopic examination of this, however, showed it to be a mass of micrococci, with a small proportion of cell-nuclei. Cultivations from this material gave only a feeble growth, which was afterwards determined to be the Staphylococcus aureus. Cultures from the blood remained sterile.

IX. Staphylococcus aureus. The same generation and solution as in the preceding case were employed, but only one cubic centimetre was injected. There was no result observed. The animal was killed on the fourth day, when only a slight redness at the point of entrance of the inoculating-needle could be made out. Cultures made from the blood and from the peritoneum remained sterile.

X. Staphylococcus aureus. Two cubic centimetres of the solution used in the two preceding cases were injected into the knee-joint of a full-grown guinea-pig (right posterior). Death on the following day. Cultures from the blood and from the joint gave a free growth of the Staphylococcus aureus; the joint itself showed no suppurative action, but was the seat of intense redness, with great swelling and some infiltration of blood. A small vessel had undoubtedly been ruptured during the inoculation, and some of the infective material had in this way got into the blood-current.

XI. Staphylococcus pyogenes albus from an abscess at an ununited fracture of the humerus (Case I.), fifteenth generation, cultivated out of the body for thirteen months. Two cubic centimetres of a culture in nutrient gelatin were injected under the skin of the back of a full-grown guinea-pig. On the second day a slight swelling was observed at the point of inoculation. The animal was killed on the fourth day, when section showed nothing abnormal in the abdominal or thoracic viscera. There was an abscess under the skin at the point of inoculation, about two centimetres in diameter, filled with quite fluid pus of a distinctly lighter color than that found in any of the preceding experiments. There was not much change in the tissues about the abscess; a very slight swelling, extending one or two millimetres from its boundaries, being all that was noticeable. Cultivations and microscopic examinations showed the presence of the Staphylococcus albus in the pus and in the abscess-wall, but not in the blood.

XII. Staphylococcus pyogenes albus. The same generation and cultivation were employed as in the preceding case. A drop of a culture in nutrient gelatin was placed in ten cubic centimetres of water, and two cubic centimetres of this were injected subcutaneously over the abdomen. The animal was killed on the fourth day, but no bacteria were found, and the point of entrance of the inoculating-needle was barely visible except upon close examination.

XIII. Staphylococcus pyogenes albus from a perinephritic abscess (Case II.), twelfth generation. In this and the following experiment, XIV., two cubic centimetres of a pure culture in nutrient gelatin were injected subcutaneously over the abdomen. Both guinea-pigs were killed at the end of a week. In both were found small abscesses at the point of inoculation from one to three centimetres in diameter, and filled with a thin yellowish-white pus. Cultivations showed the presence of the Staphylococcus albus in both, but in neither of them was anything found in the blood.

XV. Staphylococcus pyogenes albus from a diphtheritic vagina (Case VI.), thirteenth generation, cultivated outside of the body for nine months. A minute portion of a cultivation in nutrient gelatin (one-half of a cubic centimetre), with two cubic centimetres of freshly-boiled distilled water, was injected subcutaneously in the right abdominal region of a guinea-pig. A small lump was felt under the point of inoculation upon the following day. The animal was killed at the end of ten days. The lump had apparently decreased in size, for upon section it was found to be barely as large as a pea, and contained a few drops of thin pus. Microscopic ex-

amination showed that there were large numbers of micrococci in the pus and in the walls of the abscess. Cultures in nutrient gelatin and upon agar-agar showed that they were the Staphylococcus albus.

XVI. This experiment was a simple repetition of the preceding. The same culture and the same amount were used in the same way, and the results were precisely the same.

XVII. Staphylococcus pyogenes albus, fourteenth generation, from a case of diphtheria of the vagina (Case VII.), cultivated outside of the body for over nine months. One cubic centimetre of a solution of a culture upon agar-agar in distilled water was injected deep into the muscle of a leg of a guinea-pig. The animal was killed at the end of six days, when a clearly-defined abscess, about three centimetres in diameter, was found lying between the muscles, with practically no inflammatory tissue surrounding it. The pus was of the usual character, fluid, and of a rather light yellow color. Cultivations made from it gave colonies of the Staphylococcus albus, and microscopic examinations showed many micrococci in the pus and abscess-walls. Neither of these methods of investigation gave any result when applied to the blood and internal organs.

XVIII. Staphylococcus pyogenes albus. The same cultivation and from the same source was employed in this as in the preceding case. A larger amount, however,—five cubic centimetres,—was injected subcutaneously in the left abdominal region. The next day a very marked swelling could be seen, and upon the third day this swelling broke through the skin and commenced to discharge. Section showed a large abscess just below the point of inoculation. Cultivations gave the Staphylococcus albus and two varieties of bacteria, which were probably the result of contamination from the air, especially as sections of the abdominal wall showed micrococci only.

XIX. Staphylococcus pyogenes albus cultivated from a psoas abscess (Case IX.), fifteenth generation, propagated outside of the body for more than nine months. One cubic centimetre of a culture in nutrient gelatin was injected under the skin of the back of a guinea-pig. The animal was killed on the sixth day, when an abscess the size of a small marble was found at the point of inoculation. Cultures from the pus gave a free growth of the Staphylococcus pyogenes albus; nothing was found in the blood and internal organs.

XX. and XXI. The same cultivation was used in the same quantity for inoculation into the abdomen of two other guinea-pigs. They were examined on the fifth day, and in both of them localized abscesses were found at the seat of inoculation, which were shown to contain the Staphylococcus pyogenes albus by cultivation experiments and by microscopic examination of the pus and of the abscess-walls.

XXII. Staphylococcus pyogenes albus from a psoas abscess (Case XV.), fourth generation, grown outside of the body for about three weeks. A guinea-pig was inoculated on the top of the head with two cubic centimetres of a culture of this organism in nutrient gelatin. A slight swelling the size of a pea made its appearance at the end of the first twenty-four hours. Examined on the third day, an abscess about two centimetres by three in dimensions was found just under the skin, and not involving any of the deeper tissues. It contained the Staphylococcus pyogenes albus, as demonstrated by cultivation experiments.

XXIII. and XXIV. The same organism from the same source carried through four more generations, making the eighth, was injected into the abdominal cavity of two guinea-pigs, one cubic centimetre being used. Examination upon the seventh day. In one of the animals a small abscess, the size of a pea, containing a few drops of light yellow pus, was found lying just below the stomach. The abscess was clearly defined, and the neighboring structures were not involved. In the other animal an abscess about twice the size of the preceding was present just above and in front of the bladder. This also was as definitely defined as the other. Cultivation experiments showed the presence of the Staphylococcus pyogenes albus in both lesions.

XXV. Staphylococcus pyogenes albus (Case XVIII.) from an abscess of the inguinal glands, third generation, cultivated out of the body for three weeks. A guinea-pig was inoculated with one cubic centimetre of a culture of this organism in nutrient gelatin. The inoculation was subcutaneous and in the dorsal region. The animal was killed on the sixth day. An abscess three centimetres in diameter was found under the skin at the point of

inoculation, and microscopic examination showed the walls and the pus to be full of micrococci, which upon cultivation were seen to be the Staphylococcus albus.

XXVI. The fourth generation of the same organism employed in the preceding experiment was used to inoculate a guinea-pig in the abdominal cavity, one cubic centimetre of the culture in nutrient gelatin being the quantity injected. It was killed on the third day, when, as in the other cases, an abscess was found lying in the abdominal cavity just anterior to the kidney and without implication of any of the surrounding tissues. Cultures from the pus it contained showed the presence of the Staphylococcus pyogenes albus; cultures from the blood gave no result.

XXVII. This experiment was the same as the preceding, and gave the same results in every particular.

XXVIII. Erysipelas coccus (Case V.), twenty-second generation, cultivated outside of the body for more than a year. A minute portion of a colony on nutrient agar-agar was diffused in sterilized distilled water, and two cubic centimetres of the mixture were injected into the skin of the top of the head of a guinea-pig, which had been previously shaved and washed with corrosive sublimate. A marked redness made its appearance on the following day, accompanied by much swelling of the skin. An incision into the skin was made, and cultivations from the edges of the wound gave a plentiful growth of the Erysipelas coccus.

XXIX. and XXX. The same generations and material were used in both cases. The inoculations were made subcutaneously in the abdominal region in guinea-pigs; they were followed by some swelling and tenderness of the skin and general languor and disinclination to movement. Section on the third day showed marked emaciation everywhere, and much congestion of the skin of the abdomen, with some œdema. Cultures made from the skin showed the Erysipelas coccus in abundance, and sections of the infiltrated tissue were found to contain numbers of these organisms lying in the lymph-channels and between the cells of the deeper layers.

XXXI. Staphylococcus pyogenes citreus (Case III.), twentieth generation, cultivated out of the body for over a year. Two cubic centimetres of a culture in nutrient gelatin were injected into the abdominal cavity of a guinea-pig. The animal was killed on the fourth day, when a slight infiltration about the point of inoculation was found, but no suppuration and no bacteria could be demonstrated anywhere in the animal's body.

XXXII. The same material in the same amount was employed for injection into the abdominal cavity of a second guinea-pig. The animal was killed on the second day, when an abscess the size of a pea was found among the intestines, which were adherent to its borders, and the whole abdominal cavity was much congested. Cultures from the pus in the abscess and from the blood gave colonies of the Staphylococcus pyogenes citreus.

XXXIII. A small portion of a culture of the same organism upon nutrient agar-agar was mixed with four centimetres of sterilized distilled water, and two centimetres of the mixture were injected under the skin of a guinea-pig in the abdominal region. The animal was killed on the third day, when an abscess about two centimetres in diameter was found at the seat of inoculation. Cultures from the pus of this gave colonies of the Staphylococcus citreus, but nothing was found in the blood.

XXXIV. Staphylococcus cereus flavus (Case XIV.), seventh generation, cultivated out of the body for six weeks. This organism is one described by Passet ("Untersuch. ü. die articl. der eitrigen Phlegmonen des Menschen," Berlin, 1885), and which he considers to be active in the production of suppurative processes. He was, however, unable to produce any specific results in inoculation experiments with it, and the two which I made likewise gave negative results. The experiments were alike in character, and consisted in the injection into the abdominal cavity of guinea-pigs of two cubic centimetres of a culture in nutrient gelatin. Section of the first on the third day after the inoculation showed no result whatever, and cultivations from the blood and abdominal fluids failed to show the presence of any bacteria. The (XXXV.) second guinea-pig, killed on the second day, gave equally negative results, neither macroscopic, microscopic, nor bacteriological observations showing the presence of anything abnormal. The negative evidence to be offered in the case of this bacterium

does not, therefore, permit us to say that it has any pathogenic properties which can be demonstrated by ordinary methods; the only fact which is known is that of its rather uncommon occurrence in suppurative processes. Passet's specimen was found in a case of chronic suppurative periostitis of the ulna in a phthisical male subject twenty-seven years of age. Mine occurred in the case of psoas abscess in a child which was supposed to be connected with disease of the spine.

XXXVI. Streptococcus pyogenes (Case XVI.), sixth generation, cultivated out of the body for six weeks. One cubic centimetre of a culture in nutrient gelatin was injected into the shoulder of a guinea-pig. In two days, examination showed extensive infiltration of the muscles about the point of inoculation, with free suppuration and a collection of pus in the axilla. Cultures from the places affected gave colonies of the Streptococcus, and microscopic examination of the pus showed the organism in large numbers.

XXXVII. and XXXVIII. One cubic centimetre of the seventh generation of the same organism was injected into the abdominal cavity of two guinea-pigs. They were found almost moribund on the morning after the inoculation. Section showed an extensive inflammation over the whole abdominal cavity, with slight suppuration compared to the extensive nature of the process. Cultures from this region and from the blood of the heart gave abundant growth of the Streptococcus.

XXXIX. The same generation as was employed in the last two cases was used in this one. A very minute portion of a colony upon agar-agar was mixed with water and injected subcutaneously into a guinea-pig. Section upon the third day showed an extensive suppurative infiltration beneath the skin, extending out in all directions from the point of inoculation. The lymphatics all through the abdominal cavity were much congested, as were the spleen, liver, and kidneys. Cultures from the pus and from the blood in each of the organs, as well as from the heart, gave free growth of the Streptococcus pyogenes.

XL. Micrococcus pyogenes tenuis (Cases XVII. and XVIII.). Cultures of this organism were made as related in the account of the cases from which they were obtained. The fourth generation from (Case XVII.) an abscess of the arm was inoculated (one cubic centimetre of culture in nutrient gelatin), after cultivation for three weeks, subcutaneously in one guinea-pig, with no result. The third generation, from Case XVIII., a "bubon d'emblée," was injected in the same quantity and in the same way into a guinea-pig. Section in three days showed a very slight infiltration of the tissues about the point of inoculation, but cultures from this situation remained sterile. Microscopic examination showed a few of the organisms lying in the infiltrated portion of the tissues; so very few, however, as to be exceedingly difficult of detection.

In speaking of Case XV.—a psoas abscess in a child—mention was made of an organism which was found in the cultivations from that source which presented certain peculiarities under cultivation which I believe have not yet been spoken of by other observers. It first attracted attention by the peculiar green fluorescence which it imparted to the gelatin culture-medium throughout the entire diameter of the test-tube, whilst it did not liquefy the gelatin, in this respect differing from the bacillus of green pus, which does produce liquefaction of that material. The only other organism with which it can be confounded by the macroscopic appearances of its cultures is the *fluorescent bacillus*, which produces the like pigmentation of the gelatin-culture medium. This color extends beyond the limits of the colony, and bacteria are not found in it, and it seems to be due to the action of some product of the growth of the organism upon the nutrient material. In fact, so far as I have yet investigated this bacterium there appears to be no difference between the appearances of its cultures in nutrient gelatin, agar-agar, and blood-serum, the main point being that, so far as I am aware, the fluorescent bacillus has no pathogenic properties, whilst the organism which I am describing seems to have a very active influence upon guinea-pigs. Microscopically, the differences are marked, however, for this organism is a short bacillus, appearing singly, in pairs, and in chains from 0.3 μ to 0.4 μ in length, whilst very often its appearance in the tissues is that of a long rod, it being exceedingly difficult to decolorize the chain in this situation just enough to show the individual members. It grows

well at the ordinary temperature of the room, much more rapidly at 37° C. It does not liquefy gelatin, but produces a grayish-white line in the track of a needle, and in a few days a marked greenish-yellow fluorescence extending throughout the substance of the nutrient material. On agar-agar it produces in from thirty-six to forty-eight hours a grayish-white colony, elevated above the surface of the material, which has a peculiar soft, glistening appearance. The same greenish-yellow fluorescence makes its appearance throughout the substance of the culture medium. Plate-cultures made in nutrient gelatin show round points of a whitish color in two days or more; the gelatin is not liquefied, and very soon presents the same greenish-yellow fluorescence as when the cultivations are made in test-tubes.

The limits of time at my disposal have been so narrow that I have not been able to investigate this organism as thoroughly as I should wish. What I have said of it is merely a preliminary description, which I hope to fill out more in detail at a future time, and will merely mention, in addition, the inoculation experiments which I have made with it.

A guinea-pig was inoculated in the abdominal region (subcutaneously) with two cubic centimetres of the sixth generation of this organism in nutrient gelatin. It died on the following day. On section four to six hours after death, there was no localized suppuration, but the entire front of the body was as dry as if there had never been any fluids there. The skin could be readily lifted from the underlying tissues without any dissection whatever, and the muscles, particularly the pectorales, were as distinct from each other as if they had been carefully separated and all the intermuscular substance removed. In fact, the appearances were those of commencing putrefaction; there was a slight œdematous condition of the subcutaneous cellular tissue of the back. Cultures from this œdema, from the blood of the heart, and from incisions in various organs, gave colonies of the organism of which we are speaking. A little later, eight guinea-pigs were inoculated in the same way as the preceding, with the eighth generation of this bacterium. Section, in from four to six days, gave uniformly the result which is illustrated in these specimens. Nothing was found at the seat of the inoculation, but in every case the liver and spleen were found to be enlarged and the seat of a greater or less number of small abscesses. Occasionally the kidney seemed to be somewhat swollen also, but no abscesses were to be seen. Cultivations from the blood and from the seat of inoculation always remained sterile. Colonies from these abscesses always produced the peculiar fluorescence and microscopic appearances which I have attempted to describe. These include all the experiments which I have yet made in this direction. I have thought it well to speak of them here, because they seem to bear out my assertion that the end is not yet in regard to the isolation of new species of bacteria connected with the suppurative processes in man, and because I thought it might interest the members of this Association to have these facts presented to them.

The conclusions which may be drawn from the work here reported are as follows:

I. The cultivation experiments conducted over so long a space of time, with the successful inoculations at the end of that time, indicate very plainly the retention of the pathogenic power of these organisms indefinitely. Their virulence is just as great at the end of a year, and after being passed through a large number of generations, as it is when taken from their original birthplace.

II. Their permanence of form is also well demonstrated, their microscopic appearances and peculiarities under cultivation undergoing absolutely no alteration.

III. In order to obtain either a modification of their pathogenic powers or of their morphological properties,—if this is possible at all,—some different methods of observation must be used than those which have hitherto been employed.

IV. The probabilities indicate that work in this direction is not likely to be attended with much success: *a*, because no modifications have yet been observed, and, *b*, because prophylaxis furnishes the easiest and most generally applicable safeguard against the activity of these lower forms of life.

V. So far as the experiments go, they tend to show that no form of the suppurative process in man is unattended by bacteria, and that the inoculation in the lower animals of pure cultures of these

bacteria is followed by more or less acute and extensive suppuration.

VI. This conclusion—that of the dependence of the suppurative process upon the activity of bacteria—is very strongly supported by the most recent evidence of the best equipped workers in the field of bacteriological research.

VII. Very different clinical phenomena may be produced by the same organism; all of these phenomena, however, coming under the general head of the inflammatory and suppurative processes.

VIII. The differences in the results produced by the same micro-organism in different individuals depend upon causes foreign to the bacterium itself.

IX. These differences are the result of differences in the amount of the infectious material received into the system, and of the locality or lesion by which it gains access, and also by variations in individual condition,—the "personal equation" being a very large factor in making up the sum of any results in bacteriological work.

Certain investigations upon the resistance to various destructive reagents of some of these forms of bacteria have been made by Passet (*l. c.*). The organisms used were mainly the Staphylococcus pyogenes aureus and the Streptococcus pyogenes, these being selected as the most common and the most active of their class; and the reagents employed were salicylic and carbolic acids and corrosive sublimate. The results indicated the superiority of corrosive sublimate as a destructive agent, six drops of a one-per-cent. solution of this material preventing the development of either of the bacteria mentioned in ten cubic centimetres of nutrient gelatin, whilst it required twenty-five drops of a five-per-cent. solution of carbolic acid or one hundred drops of a solution of salicylic acid (one to three hundred) to do the same thing.

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, A.M., M.D.,
Professor of Otology, Philadelphia Polyclinic.

PAINLESS OR ONLY SLIGHTLY PAINFUL ULCERATION AND PERFORATION OF THE MEMBRANA TYMPANI, PROBABLY OF A TUBERCULAR ORIGIN.

DR. ALBERT H. BUCK (*New York Medical Journal*, August 21, 1886) during the past year has observed three cases with the above-named features, which he believes to have been characteristic of tubercular origin.

His conclusions respecting the distinguishing features in tubercular inflammation of the middle ear, in its incipient stages, are—

1. The tendency to localize itself in the vicinity of the upper and posterior portion of the membrana tympani. Whether the disease originates in the tympanic mucous membrane, in the fibrous structures of the membrana tympani, or in the bone of the immediate vicinity, Dr. Buck is unable to say, though he suspects that in some cases the bone-substance is the starting-point of the disease.

2. The marked insignificance of the pain, or even its entire absence.

3. The intolerance of any but the simplest and gentlest local remedial measures.

Dr. C. J. Blake, of Boston, in a letter to Dr. Buck, *à propos* of this paper, furnishes some new data, and suggests an explanation of the preference shown by the disease for the upper region of the tympanic cavity.

He has had several cases of purulent inflammation of the middle ear accompanying pulmonary tuberculosis, and characterized by the following symptoms:

1. Painless course of the inflammatory and destructive process, which occurred in the upper portion of the tympanic cavity, beginning with congestion of the inner end of the external auditory canal and membrane of Shrapnell and circumjacent region, followed within forty-eight hours by œdema of the parts mentioned, ulcerative perforation of the membrane of Shrapnell, rapid sloughing, and free purulent discharge.

2. But two of the cases were examined for bacilli in the discharge from the ear, and in neither case were bacilli found.

Dr. Blake thinks the initial impulse to the implication of the middle ear, occurring usually in the upper part of the tympanic cavity, comes from vaso-motor inhibition, reflexly from the lung-disease in that tract supplied largely by the tympanic branch or branches of the carotid, rather than, as Habermann * supposes, from infection from the sputa.

TREATMENT OF SUPPURATION OF THE TYMPANIC CAVITY.

Dr. C. Miot, in an article read before the French Otological and Laryngological

* Präger Med. Wochenschrift, No. 6, 1885.

Society, April, 1886 (*Annales des Maladies de l' Oreille*, etc., July, 1886), makes some interesting and valuable suggestions regarding the treatment of suppuration of the middle ear. He is not entirely in favor of either an exclusively moist or dry treatment, but seems to rely upon the instillation of drops for the cure of this disease rather than upon the insufflation of powders. He then mentions some of the solutions which have proved most useful in his hands. The best antiseptics are not always the most efficacious remedies in this disease, according to his observations. Preference is given to a strong decoction of poppy-heads, to which one part of boric acid is added to each one hundred parts of the fluid, in order to prevent the decomposition of the decoction. Solutions of cocaine rapidly calm the ear-pain in the majority of cases, but they sometimes augment the congestion of parts already inflamed, by paralyzing for too long a period the nervous supply.

In the preparation of astringent and antiseptic solutions preference is given to those made with pure glycerin, because they do not readily undergo changes and are tolerated by the mucous membrane of the ear.

As examples are given—

1. Borax 1 to 3 gr., 30.
2. Subacetate of lead 1 to 3 gr., 30.
3. Sulphate of aluminium 1 to 2 gr., 30.
4. Crystallized phenic acid 3 to 30 gr., 30.

To these solutions chloral may be added in varying proportions in order to render them more efficient.

5. Water oxygenated to seven volumes (formula of Dr. Baldy) and mixed with three, five, or ten parts of water.

Caustic Solutions.—As instillations are employed one-twentieth to one-tenth aqueous solutions of nitrate of silver, or a one-fifth to one-third of chromic acid. For touching diseased surfaces, one-tenth to one-half strength solutions of nitrate of silver, and of chromic acid from one-third to saturation, and also a saturated alcoholic solution of crystallized phenic acid.

Substances which make the most efficacious powders for insufflation are boric acid, iodoform, sulpho-carbolate of zinc, and sugar (*candi*),—the former either separate or commingled with sugar or magnesia. Powdered sugar acts well as a detergent upon surfaces covered with granulations. Iodoform and sulpho-carbolate of zinc are of service in strumous cases, in which the mucous membrane granulates easily and becomes fungoid. We should be on our guard when using iodoform, and cease employing it as soon as it seems to produce constitutional disturbances, especially in the digestive tract.

Indirect Means.—In acute cases, with pain, abstraction of blood by means of leeches is considered more prompt than irrigation by hot water.

We cannot agree with the author in his views as to the beneficial effect of derivatives on the mastoid (blisters, tincture of iodine, and the galvano-cautery) in controlling chronic suppuration and the growth of granulations in the middle ear.

General Treatment.—It is believed that suppuration of the tympanum can be cured in the majority of cases by local treatment. General treatment is useful only in modifying the diathesis of the subject, and to prevent relapses or to render them less frequent.

The treatment of adjacent parts which influence the state of the ear is considered an absolute indication. Suppuration of the tympanic cavity must, of course, be considered in its chronic and acute stage. The latter must be modified at once, as can be done by the use of antiphlogistic methods.

When the perforation is small, the inflammation may abate with ordinary treatment. On the contrary, if the running from the ear persists, with exacerbations more or less frequent, the perforation should be enlarged, in order to facilitate the escape of pus and the ready treatment of the drum-cavity.

In cases of simple otitis media suppurativa without much swelling of the mucous membrane, solutions of borax, subacetate of lead, and of sulphate of alumina, as well as insufflations of powdered boric acid when the discharge is not copious, may be employed. When the mucous membrane is more thickened, the same solutions, with the addition of chloral, may be used, alternating their application every eight or ten days. When powdered boric acid is to be used, it must be put into the canal in quantity sufficient to exclude all air, and renewed according to demand.

In cases of small granulations on the surface of the auditory canal, the membrana tympani, or the mucous membrane

of the drum-cavity, it is recommended to lightly scarify and apply caustic solutions,—a method, in our opinion, devoid of any merit, as insufflations of boric acid, either alone or associated with hydrastin or resorcin, will accomplish their destruction more easily and simply. The cure the author attributes to the scarification is most probably due to the alkaline washes and the use of borax and resorcin solutions, and the final dressings with powdered boric acid.

Polypi should be promptly removed, and "some hours afterwards or the next day the pedicles should be cauterized with chromic acid, carbolic acid, nitrate of silver, or the galvano-cautery, according to the effect desired." Why this delay of hours in touching the pedicle is advised we are not informed, but we believe it an unusual delay. In the interval of the cauterizations, which are recommended from every two to ten days, the instillations already named are advised, and, when the discharge becomes slight, the insufflation of powdered boric acid.

In the chronic state the perforation may be narrow and indicative of different conditions. Such cases are divided by the author into several categories.

In the *first* group the suppuration has lasted for many years, and has never ceased, notwithstanding the prolonged and rational treatment. In such instances it is fair to assume the presence of a sequestrum or of granulations which maintain the discharge. Before, however, instituting any special treatment for their removal,—like, for example, sulphurous acid, as recommended by Andeer,—we are advised to prescribe the astringent solutions considered the best by Miot,—viz., sulphate of alumina and chloral. The discharge may cease in a few days with this treatment.

In a *second* group a discharge may have existed for a long time, and about the edges of the perforation there may be a polypoid mass. Upon the destruction of these granulations by astringent solutions the discharge ceases in a few days.

In a *third* group a neoplasm in the drum-cavity may have extended through the perforation, and have developed in the auditory canal. After removing all the growth obtainable outside of the drum, and cauterized the remnants in the drum-space, the neoplasm may reappear notwithstanding numerous applications of the galvano-cautery. Sometimes a more energetic effect is obtained by the use of crystallized carbolic acid, a less efficient one by chromic acid. If the masses still grow afresh, the perforation in the membrana must be enlarged by means of the galvano-cautery, according to Miot, and then we shall be able to get at the polypoid growth and destroy it.

In the *fourth* group not only the membrana flaccida (Shrapnell's membrane) is destroyed, with neighboring parts, but also very often the upper wall of the osseous canal near the drum is eroded. These suppurations are very fetid. If treatment is not soon followed by relief, the following course is recommended. A delicate and flexible laminaria probe is introduced into the drum-cavity and passed in all directions. Generally neither carious bone nor polypi are met, but a soft, pultaceous, very fetid, purulent mass, resembling softened tubercle, filling the entire drum-cavity. As it is not easy to get this mass from the drum-cavity, a small counter-opening two to three millimetres wide should be made with the galvano-cautery, which will permit of still further examination of the tympanic cavity with a probe, but also to inject an alkaline wash or an antiseptic morning and evening.

The following are recommended:

1.—Tinct. of iodine, 4 grms.;
Distilled water, 40 grms.;
Iodide of potash, 1 grm.;
Rectified alcohol, 2 grms.

2.—Sulphate of alumina, 1 grm.;
Distilled water, 40 grms.;
Hydrate of chloral, 0.03 grm.

3.—Crystallized carbolic acid, 3 grms.;
Pure glycerin, 30 grms.

If these preparations do not give relief in a few weeks, there should be no hesitation in employing injections of iodine or of nitrate of silver in solution, in strength of $\frac{1}{40}$ to $\frac{1}{20}$, taking care to neutralize the excess of caustic and to wash out the masses of chloride of silver, as they are considered irritants. By a repetition of the caustic injections, and alternating them with astringents and antiseptics, and "by the employment of revulsives on the mastoid," it is possible to check discharges of long duration. In the *fifth* group the

membrana may be perforated in more than one spot, and the introduction of a probe sometimes reveals the presence of a sequestrum acting like a foreign substance. In such an instance the portion of the membrane connecting the two perforations should be incised and the sequestrum removed.

EXSECTION OF THE MALLEUS.

Kretschmann has reported three cases of exsection of the malleus, during the past year, for caries (*Universitäts-Ohrenklinik zu Halle*, 1885; *Archiv für Ohrenh.*, Bd. xxiii., July, 1886).

The first case was that of a man 44 years old. In addition to the caries of the hammer there was a perforation in Shrapnell's membrane, and a second one beneath the end of the manubrium. The suppuration was slight, but fetid. The patient complained chiefly of tinnitus and dizziness, in addition to hardness of hearing. The malleus, with the entire remnant of the membrana tympani, was removed without anæsthesia. The hammer, examined carefully after removal, was found to be carious throughout. The subsequent treatment consisted in syringing through the Eustachian tube. The dizziness and tinnitus ceased after this operation. In fourteen days the patient ceased to return for observation.

The two other cases were those of young girls 16 years old, in whom the entire membrana tympani was wanting. The fully-exposed malleus was in a horizontal position and was *strikingly white*. At the end of the malleus there was found on several occasions a drop of pus.

In one of these cases the removal was effected with difficulty, without any noteworthy effect upon the suppurative process; and in the other case the operation was not fully completed.

Dr. Samuel Sexton, of New York (American Otological Society, July 20, 1886), has recommended

A NEW OPERATION FOR THE RADICAL CURE OF CHRONIC INFLAMMATION OF THE MIDDLE EAR-TRACT.

The author, having observed that in a number of cases where the transmitting mechanism had been lost a spontaneous cure of the purulent running ensued, concluded to imitate the curative action of nature and remove the ossicles, in order to insure thorough drainage from the tympanic attic and other parts of the tympanum.

The operation was tried on a case of long-standing purulent inflammation of the attic of the tympanum. In order to avoid the danger of using an ordinary lamp in connection with the administration of ether, an electric lamp was employed. Since then Dr. Sexton has performed the operation, as he informs me in a recent letter, in thirty cases.

The first step in the procedure is to separate the membrana flaccida (Shrapnell's membrane) from the edge of the auditory plate, and to remove any portion of the membrana vibrans still adherent to the auditory ring. If the malleus and incus remain *in situ*, it is well to divide the tendon of the tensor tympani, if still adherent.

The chorda tympani is then divided, if present, where it enters the tympanum at the pyramid, and also at its exit into the canal of Huguier. The long process of the malleus, with the chorda, may also be detached and removed from the glenoid fissure. The detached portions may be removed with forceps. It will be frequently found that the incus has been detached, but still remains. It may be removed with the attic-scraper, which is to be introduced from below and passed up along the inner wall of the tympanum, when the distal extremity may be carried over the incus or malleus, if the latter bone remains, and by traction the ossicles can be detached. Polypoid masses, granulation-tissue, and the products of inflammation may now be removed with the cutting curette or cutting forceps, and the parts dressed with a four-per-cent. solution of cocaine to relieve pain. There is usually free bleeding during the operation, often sufficient to protract it and increase its difficulties. "The effect of injury or destruction to the chorda tympani nearly always manifests itself in some way," but in Dr. Sexton's experience it had never been of serious import. Disturbances of taste sometimes follow the operation, but they gradually disappear and leave the sense of taste unaffected.

The drum should be kept well cleansed, and light dressings of powdered boric acid applied until healing takes place. The salicylic acid powder may also be applied as freely as it can be borne. In some

cases this powder seems to irritate at first, but gradually a tolerance is established.

In the cure resulting from this treatment dermic transformation of the tympanum takes place, but mucus may occasionally gain admission from the Eustachian tube during head-catarrh or on blowing the nose. This should be frequently removed with absorbent cotton, and if necessary the drying application renewed for a time.

Dr. Sexton says he would not hesitate to perform this operation when the incudo-stapedial joint remains intact, unless a very considerable portion of the membrana vibrans is present.

PURULENT OTITIS SUBSEQUENT TO THE PUERPERAL STATE.

Bonnet reports (*Annales des Maladies de l' Oreille*, September, 1886) a case of a young primipara, 24 years old, who was delivered artificially, and with great suffering, of a dead child. Subsequently the patient seems to have been affected by absorption of purulent matter, because the antiseptic measures were not kept up long enough. The germs thus allowed to introduce themselves into the general organism from the affected uterus accomplished their migration in an insidious manner until their presence was suddenly and unexpectedly revealed by an attack of otitis media suppurativa on the left side four weeks after the departure of the patient from the Hôpital Bichât, Paris. From this otitis the vessels of the tympanum and of the neighboring osseous structures, direct or mediate tributaries of the inferior petrous sinuses, and those of the mastoid, to which the inflammation was also propagated, and which flow into the lateral sinus, were attacked first with peri- and then with endo-phlebitis. Propagation to the sinuses and extension to the internal jugular vein were not slow to follow. From this nidus, progressively developed, it is easy to follow the septic emboli, which, becoming detached, were finally arrested in the ramifications of the pulmonary artery, and thence infected the entire circulation.

The clinical observation of the case corresponded exactly with the aforesaid anatomical course of the disease.

The right hemisphere of the brain was congested, the left was pale. The arachnoid liquid was in normal proportions, and its limpidity was preserved. There was neither meningeal nor cortical lesion apparent. The meninges were not adherent. The cerebral hemispheres were normal. That portion of the left cerebellar hemisphere corresponding in position to the lateral sinus on this side showed on its surface a grayish spot about the size of a franc. This lesion was entirely superficial. The central portions were healthy, as were the entire right hemisphere and the isthmus of the brain. The medulla presented no macroscopic changes. On a level with the left lateral sinus, the internal surface of the dura mater presented a greenish-yellow discoloration over a space the size of two francs, and this discoloration extended to the point of the pyramid of the petrous part of the temporal bone. This membrane, which was but slightly adherent to the internal surface of the temporal bone, was easily lifted, and then revealed the fact that the descending portion of the lateral sinus had become transformed into a purulent nidus, extending posteriorly as far as the turn of the sinus, and anteriorly as far as the summit of the petrous pyramid, embracing the inferior petrosal sinus.

The osseous wall forming the external limit of the nidus displayed the slate color of superficial necrosis, and the dura mater forming its internal wall manifested no thinning nor perforation. Pus extended into the internal jugular vein, the walls of which were thickened and its cavity filled with a pyo-sanguinolent mass. The other sinuses contained liquid blood, with here and there non-adherent, non-purulent clots.

A series of sections of the mastoid and petrous portions of the temporal bone showed that the tissue of the mastoid was denser than normal, infiltrated with a slate-colored fluid, but without destruction of its cells, which contained no pus. The middle ear and the auditory canal were filled with pus. The uterus had not undergone complete involution nearly two months after delivery. The ear-disease set in about five weeks after the confinement.

Dr. Bonnet suggests that if the sulphate of quinia had been taken regularly and in larger doses, and had the antiseptic injections been repeated both in the ear and in the vagina, the number and intensity of the disease-germs might have been reduced, and the fatal result warded off, and finally an entire cure might have been effected.

A CASE OF APHASIA, WITH REMARKS.

Read before the New York State Medical Society, Third District Branch, meeting at Binghamton, Sept. 17, 1886,

BY S. M. HAND, M.D.,

Norwich, New York.

I WILL first report a case of aphasia which came under my observation, and then make some comments on its peculiarities which are points of interest in a study of this curious infirmity.

The case was Mrs. C. G., aged 57. On the 2d of May, 1878, she was suddenly seized with a severe pain in her head while sewing, and immediately fell from her chair. She was placed in bed; was drowsy, and for a time could not move her right side. Called to see her immediately, I found her almost insensible, with incomplete right hemiplegia. As she was a plethoric woman and in pretty strong, healthy condition prior to this attack, I bled her from the arm, taking about a quart of blood. After the bleeding she awoke to almost normal consciousness, and the power of motion in the affected side rapidly increased, so that within a few hours she had become able to raise her hand and move her foot, although it was difficult. About the third day she lost her speech, although she had previously been able to answer questions and express her wants. The paralysis then gradually increased until within a few hours she had complete hemiplegia of the right side, with total loss of speech, and could not express a thought by any means but gestures accompanied by utterance of the sound "lockey." She was confined to her bed three or four months, but appeared to have as perfect intelligence as usual, and gave attention to the concerns of the farm and the work about the house. For several months she could not articulate a single word, not even yes or no. On September 1 she had four convulsions within two hours, and the next day had three more; in the intervals she appeared clear in her mind. On the 15th of November she had one convulsion, but has been well since then to the present time.

Six or eight months from the hemiplegic attack she could only speak the word "no;" weeks afterwards she could say "yes," with the usual "lockey-lockey." After about two years had passed of this aphasic condition I asked her to pronounce the word "welcome," and she made the attempt, but only said "lockey-lockey," as usual. Then I asked her to speak it after me as quickly as possible after I spoke it, and as I pronounced the word she said "welcome" as perfectly and plainly as she had ever done; but pausing an instant, she had forgotten, and only could say "lockey-lockey," and shook her head, saying "no, no," and wept on account of her failure; still she could repeat not only it, but also many other words after I spoke them, if she did so quickly after hearing them pronounced. But from the commencement to the present she has not probably articulated more than a dozen different words. She has by accident spoken a word or two, but could not repeat them. The past year or two she has been able to call the name of her daughter Phœbe voluntarily when she desires to; yes and no and Phœbe are the only words that her vocabulary yet includes for her voluntary use, except "lockey," which she can speak very glibly; she can count and express numbers by raising her fingers. She has the same disability for reading and writing that she has for speaking; she cannot point out her own name in a column of women's names; although she can voluntarily speak her daughter's name, Phœbe, she is not able to recognize it when plainly printed; she cannot express a single word in writing, but can copy a letter or a word. Her general health appears to be perfectly good, so that she rides out and visits her friends as she did before the hemiplegic attack, and, save her hemiplegia and aphasia, she is apparently in good physical and intellectual health.

This case is important to us not on account of its treatment, but more particularly because it is one of a kind that illustrates the localization of brain-function, for it is, of course, recognized as a case of amnesic aphasia.

I had worked out the instructions of some of the different authors that treat of this disease, and had designed to use it in connection with the report of this case, but I find it so long that it would not warrant the expectation of your attention and patience.

The principal object of this compilation of sentiment and quotation of the opinions of authors is to call attention to the admitted conclusions of experimenters in regard to the localization of the functions of the brain, in order to reach one particular faculty that has more recently perhaps than many of the others received the attention of investigators,—*i.e.*, that of articulate speech,—and to locate the lesions due to the disease, or accompanying the disease, of the brain called aphasia.

There are various theories relating to the localization of the organ or organs of language. The process of speech is a very complicated action, including an appreciation of the meaning of words, the physiological activity of a speech-centre, and the action of those parts of the brain

which are concerned in the perception of the qualities of the object signified by the word, and an expression of the conception in articulate sounds or speech.

There are many derangements of speech, and each disability of whatever kind may have a specific name and a description.

Speech has been called "the mirror of the human mind" when it is correct and natural, but it is no more a mirror of the natural and healthy condition of the mind than it may be of the morbid disturbances of the same.

Delirium is a reflection of perverted conceptions; mania is a reflection of a wilder whirlwind of thought; while idiocy and dementia and imbecility and melancholia indicate a slow and torpid flow of ideas. In all these conditions speech indicates to us not the thought which the words properly express, but the condition of the organs which were concerned in the processes of the expression; and while the speech itself may be correct as to sound, it becomes a symptom of the disturbed condition of the perceptive and intellectual activities.

Hence Kussmaul divides all derangements of speech as an independent faculty into two kinds: those of articulation and those of diction.

Articulation is only a motor act by the external organs of speech. All lesions of articulation, such for instance as stammering, have been supposed to be what he calls *dysarthric disturbances of speech.* There may be mechanical defects in the speech-producing apparatus, such as hare-lip or fissured palate, or paralyzed vocal cords, or even defect of motor nerves that govern the power of expression. This he calls *dyslalia. Diction* is a compound action of both intellectual and sensory activity. It combines words with perceptions, and at the same time so arranges them in proper order that they give expression to the flow of thoughts. But this power is subject to derangement or disturbances, and either cannot at all or cannot correctly give expression to the thoughts. These conditions of articulation and diction become mixed in many ways. Sometimes disturbances of both articulation and diction exist in the same case. In another individual the thought may be faulty while the expression is correct. In still another the thought may be correct, but have a defective expression.

These disturbances in talking, whether of articulation or of diction, or mixed in the various ways that are possible and occasionally observed, Kussmaul calls by the general name of *dysphrasia.* He describes all the dysphrasic derangements of speech which are usually comprehended under the general name of aphasia as ataxic aphasia, amnesic aphasia, dumbness for words, paraphasia, agrammatism, akataphasia.

1. Ataxic aphasia is an incapacity for the motor co-ordination of words, and appears under his first division of derangement of articulation. In this form of aphasia the patient is unable to articulate words, and yet has the power to read written language or to communicate his ideas by writing.

2. Amnesic aphasia is an incapacity for the recollection of words, and appears under the second division. In this form of aphasia the patient is unable either to speak or to read or write words. The internal word is lacking in amnesic aphasia, while in ataxic aphasia the production of the word is affected. In amnesic aphasia there is an inability to call to mind the words of language, while in ataxic aphasia there is a loss of the motor power of articulation; while all the organs of speech in both kinds are retained, and the understanding and the comprehension of the patient is perfectly good and natural, and he is able to understand words and language when addressed by others.

3. Dumbness for words is an inability, with good hearing and sufficiently preserved intelligence, to understand words. The sound of the word is heard as in health, but the image of the thing which the word signified is not presented to the patient's mind readily, if at all.

4. Paraphasia is an inability to properly connect word-images and the corresponding conceptions; so that, instead of the ones which correspond to the sense, misplaced or entirely incomprehensible word-images present themselves to the patient, and he uses a medley of words without a consciousness of it.

5. Agrammatism is an inability to form words into sentences or arrange them in proper order.

According to this classification, the case reported is one of amnesic aphasia, in which the disturbance was of diction and not of articulation, either in the external organs of speech or in the motor activi-

ties, because my patient can repeat the word plainly when her memory is prompted by having it spoken in her hearing; and also because of the impossibility of speaking the word when seen in written form, or of knowing it when so seen, or of speaking it when suggested by a question or when produced by writing.

An editorial published in the *Medical Record* of September, 1885, contains a description of aphasia in new names and divisions. Instead of the two types of amnesic and ataxic first made out by Bouillaud, Trousseau, and Broca, it is recommended to drop them and use the newer terms of motor and sensory, or aphasia of transmission and aphasia of reception. It describes motor aphasia of two kinds: aphemia, or loss of memory of the co-ordinated movements necessary to speech, and agraphia, or loss of the co-ordinated movements of writing. It locates the lesion of aphemia at the foot of the third left frontal convolution, and the lesion of agraphia at the foot of the second left frontal convolution. The sensory aphasias are divided into two kinds: psychical (or word) blindness, and psychical (or word) deafness. In the first kind the patient talks and understands what is spoken to him, but cannot understand or read written language. Here the lesion is located in the left inferior parietal lobule. In psychical deafness the subject can talk and read, but does not understand spoken language. The lesion here is in the first left temporo-sphenoidal convolution.

These new phases of aphasia were found by Marce, Kussmaul, and Wernicke, and they called them sensory aphasia, and divided them, as above stated, into two forms, psychical deafness and psychical blindness. But the later works of Hammond and Foster and Loomis and Ferrier describe the aphasias under the old divisions. Perhaps the new divisions would more conveniently take in the almost endless variety of the defects of speech, and more definitely admit of classification under one type or the other. But the defects of language are so mixed and complicated that subdivisions would often be needed, or even a resort to the old divisions of Kussmaul for a nomenclature.

There is nearly a uniformity of agreement that there is a speech-centre, or that there is a right and a left speech-centre; but, out of all the teachings and speculations of these able investigators, is it not evident that there are right and left *speech-centres*, so that perception of the qualities of objects or sentiment originates in one area or centre, and that the word-image is originated in its own area or ganglia or centre, and that co-ordination of the speech-muscles as a faculty exists in still another? The medulla oblongata includes a centre for the power of respiration, with its neighboring convulsive centre, the vaso-motor centre, the cardio-inhibitory centre, and several other powers. These various functions, although of themselves simply physical and largely involuntary, may be excited to action by psychical agency in the hemispheres. So the function of speech-making has many united and co-ordinated processes when done in perfection, and many strange manifestations when disease or violence inhibits a part of the process and so interrupts the harmony of the different actions that results in articulate speech.

(To be continued.)

TRANSLATIONS.

Treatment of Iritis.—Trousseau has formulated the following treatment for iritis. In order to prevent synechia, a one-per-cent. solution of neutral sulphate of atropine is prescribed, of which two to three drops are to be instilled every hour into the eye. In case symptoms of toxic action of atropine appear, morphine may be given hypodermically and coffee-infusion used as a throat-wash. Duboisine may be substituted for the atropine, and used in the same manner, without giving rise to unpleasant symptoms. It is a good precaution at the moment of the instillation always to compress the lachrymal sac, so as to prevent the collyrium from entering the nasal fossæ and the throat.

The pain may be relieved by (1) frictions upon the brow of extract of belladonna (one part) to ointment of mercury (three parts). Leeches may be applied to the temples with benefit, especially at the beginning. Warm applications to the eye, of cataplasms or compresses made with an infusion of the leaves of belladonna or hyoscyamus, give great relief. In cases suffering severe pain, hypodermic injec-

tions of morphine and chloral internally may be needed.

When the exudations upon the iris are abundant, even if the patient be not syphilitic, systematic inunctions should be made daily with four grammes of mercurial ointment, and iodide of potassium (from eight to thirty grains daily) given internally. Rest in bed is often of service; purgatives are often useful.

If the iritis be of syphilitic origin, one or two pills of (five centigrammes) protiodide of mercury, or of one or two centigrammes of corrosive sublimate, or the sirop Gibert, according to the period of the syphilis. Salicylate of sodium may be given, three to six grammes daily, in rheumatic cases. If the disease tend to become chronic, the treatment should be insisted upon, and especial reliance given to alterants. In all cases it is necessary to protect the eye from exposure to the light.—*Revue de Thérapeutique*, No. 14.

On the Determination of the Absolute Acidity of the Fluids of the Animal Economy.—At a recent meeting of the Académie des Sciences, M. Berthelot read a note from M. A. Blariez which contained the following conclusions: It is impossible to determine in phosphoric acid the absolute proportion of the base, inasmuch as a molecule of fluid can combine, according to circumstances, with one or two equivalents of the base, or even more. The quantity of the base which combines with the acid is variable, and is influenced by the surrounding conditions. These experiments verify M. Berthelot's statements, made after his calorimetric researches on this substance.

Phosphoric acid and phosphates are contained in the constituent principles of the fluids of the animal organism. It is therefore impossible to determine the absolute acidity of these liquids in presence of bodies which combine with the base in quantities that vary according to the surrounding media to produce theoretical neutralization.

Hydrastis Canadensis in the Treatment of Uterine Congestions, Menorrhagia, and Metrorrhagia.—J. Chéron (*La France Médicale*, No. 91) writes enthusiastically with regard to the use of hydrastis in uterine disorders accompanied by congestions or hemorrhages. The dose is usually from fifteen to twenty drops of the tincture given three or four times a day. A good formula is the following:

℞ Tincturæ hydrastis, 4 gr.;
Elixir., 20 gr.;
Syrup., 30 gr.;
Aquæ destillatæ, 120 gr. M.

To be taken in eight doses in the course of two days. Or berberine phosphate or hydrastin hydrochlorate may be given in doses of two centigrammes; four pills a day, one at each time. Hydrastin may be given in ten-centigramme doses, in pill, several times daily. This medicament, so very useful in the cases just mentioned, is also a remarkable modifier of atonic dyspepsias and catarrh of the stomach, which is not to be despised when we contrast this action with that which is exerted upon the alimentary canal by the ergot of rye.

For Pigmentation of the Skin.—In a communication to the *Journal des Comm. Médicales*, Professor Henry Leloir recommends the following for the removal of melanodermia:

℞ Chloroformis, 100;
Acid. chrysophanic., 15. M.

The part is to be washed with tincture of green soap, or simply with alcohol, and the above solution applied to the surface. When dry, "traumaticine" (guttapercha dissolved in chloroform) is painted over it as a protective, and when this comes off, in a few days, another application is made, and so on. This treatment is applicable only to the epithelial melanodermia. In the so-called dermic melanodermias (when the pigment is deposited in the derma and not the epidermis), its action appears to be null.—*Revue de Thérapeutique*, No. 14.

New Application of the Electro-Magnet.—In a case of a man who claimed to have swallowed an iron fork, M. Trouvé brought his ingenuity to bear upon the diagnosis, at the request of M. Polaillon. An electro-magnetic needle was deflected by the approach of the patient, and a large electro-magnet caused a slight arched projection of the surface of the abdomen, as if something inside were pressing outwards. Gastrotomy was successfully performed, and the stomach was relieved of a fork twenty-one centimetres long. The wound of the stomach was sutured and left free in the abdomen.

EDITORIAL.

BACILLUS TYPHOSUS.

THE bacteriological studies of Eberth, Klebs, Koch, Meyer, Volkman, Gaffky, and others, have established the fact with a reasonable degree of certainty that in enteric fever a bacterium of characteristic morphological and biological traits, the *bacillus typhosus* of Eberth, is almost constantly present. This micro-organism occurs in the form of slender, mobile bacilli, 2.5 μ in length by 0.8 μ in width, which in cultures increase in length and then show worm-like movements (Huber-Becker). Under ordinary circumstances it does not form spores, but when kept for three or four days at the temperature of the body endogenous spores are developed. Unlike other bacteria, its capacity to retain aniline dyes is not increased by warmth. Gaffky states that these bacilli are best stained in an alkaline solution of methyl blue. Carl Seitz concludes an elaborate study of the whole subject of the etiology of enteric fever (Typhus-Aetiologie), from the bacteriological stand-point, with the following statements. In the greater number of the bodies of persons who have died of enteric fever collections of typhus bacilli are found in the different organs, and especially in the spleen. These micro-organisms may be detected in the tissues and isolated in pure cultures without difficulty. They are not found in other infectious diseases nor in other lesions of the intestinal tract. They are characterized by active movement, the peculiarity of their growth upon potato, great power of resistance to desiccation and to cold. To the question, Are these microbes the specific cause of enteric fever? it may be replied that, injected into the veins or given by the mouth, they are capable of causing morbid states in different kinds of animals. By means of infection through the blood-current, lesions presenting the microscopical appearance of enteric fever in the human body were produced. The small intestine, and especially its glandular structures, react to the infection *per os* and by way of the blood with changes resembling those of ileo-typhus. Assuming that the typhus-bacillus is the actual cause of enteric fever, the *abdominal typhus* of the Germans, we may, from experiments upon animals, very positively infer that the intestinal canal is the structure of access, since we here find the most pronounced changes, since the presence of this bacillus has been frequently here established in the living, and, finally, since here the conditions for its development appear to be the most favorable. Against the view that the bacilli find access to the organism by way of the respiratory tract is the fact that there are no marked primary pulmonary lesions.

Seitz concludes from his experimental studies that the typhus-bacillus may exert from the intestine outward, without passing into the blood-current, a deleterious or toxic influence upon the organism at large. This is the more probable since—as Hoffmann and Zenker have shown—the lesions of the various organs, except the spleen, in enteric fever are altogether out of proportion to the limited number of typhus-bacilli which can be discovered in their tissues.

Wolfhügel, Riedel, and Meade-Bolton have experimentally shown, and Michael has positively established in practice, that under favorable circumstances the bacilli multiply in water, and that in a less favorable temperature they preserve a continued existence. The long-recognized danger of infection by means of polluted drinking-water is thus placed

upon a scientific basis. Wolfhügel and Riedel, Auerbach, Green, and Shirley-Murphy have also demonstrated the possibility of the transmission of enteric fever by means of milk, which is a very favorable nidus for the typhus-bacilli. The danger of infection by means of the dejections, soiled linen, vessels, etc., is to be kept constantly in mind, while some clinicians go so far as to assert that the disease may be *directly* communicated from the patient to his attendants,—a view not generally held at present either by American or British physicians. Wagner and Pfeiffer have recently called attention to the important *rôle* which individuality and family predisposition play in the susceptibility to and toleration for enteric fever, a matter long since observed by Levick and others in this country.

The telluric influence—the part played by various soils—in the preservation and spread of the typhus-bacillus is yet to be worked out.

Much is yet to be done before the views of the more advanced bacteriologists can be finally accepted. But the evidence accumulates and light grows clearer. Are we soon to replace our hypothetical "infecting principle," our vague "contagium," by a positive, demonstrable entity in the causation of enteric fever, as has already been done in others of the group of the infectious diseases?

MEETING OF THE EXECUTIVE COMMITTEE OF THE NINTH INTERNATIONAL CONGRESS.

ON the 11th inst. an important meeting of the Executive Committee of the Ninth International Congress was held at Pittsburgh, in this State, at which the different parts of the country were well represented. It was found that affairs are progressing so well that at this date no doubt whatever can be entertained that a successful, creditable, and truly "international" Congress will be held, according to the terms of the invitation originally extended by the American Medical Association on behalf of the profession of these United States.

The Executive Committee had been quietly and earnestly at work, and had succeeded in perfecting the organization to such an extent that further meetings for this year were deemed unnecessary. Some minor details were assigned to various subcommittees, to report to the Committee, at Chicago, on the Monday preceding the next meeting of the American Medical Association. At the Pittsburgh session reports were made by the Presidents of the several Sections, showing a full organization, and a very gratifying array of able papers. The Committee on Arrangements at Washington was also fully organized, and reported much interest in the Congress taken by representative Washington physicians and numerous wealthy and influential citizens. Plans are being formed to secure much diminished rates from steamships and railroads, as well as at hotels. Even at this early date, there can be no doubt whatever of the successful results of the efforts to welcome and entertain our foreign guests in a suitable manner. The representatives of several foreign governments have already shown an active interest in the Congress, and the Belgian government has notified the United States authorities that Dr. L. Servais, of Amsterdam, has been appointed to represent Belgium; so that it is evident international preparations have auspiciously commenced.

From the energy and activity with which the preliminary organization of the Congress is being conducted, there can be no doubt of such an assembly as will be creditable to our country and to the medical profession of the United States. Sir Thomas Longmore, Sir Dyce Duckworth, Sir B. Walter Foster, Mr. Ernest Hart, Mr. John Eric Erichsen, Sir Joseph Fayrer, Morell Mackenzie, and Sir William Stokes are among those accepting from

Great Britain; whilst Charcot, Lieutaud, Dujardin-Beaumetz, Bordia, Bouchut, Cadet de Gassicourt, and Grancher represent France; and Monti, Vogel, Widehofer, Von Hebra, Liebreich, Oscar Lassar, Ottakar Chiari, and Schnitzler will illustrate, with very many others, the profession of Germany. Professor Moncorri at present represents Brazil, but many others are coming, and the promise of a large European representation grows daily.

The marked attention paid to Dr. Davis and other Americans at the meeting of the British Medical Association at Brighton, and the favorable attitude of the *British Medical Journal*, the *Lancet*, and some of the Continental journals, taken in conjunction with the decided change of tone in the comments made by some of the leading opponents of this Congress in this country, are favorable indications which are fully appreciated by its friends, as well as those of the American Medical Association.

LEADING ARTICLES.

HÆMOGLOBINURIA.

THE appearance of blood-coloring matter in the urine is the expression in most emphatic form of a preceding hæmoglobinæmia. In health the blood-plasma of man does not contain hæmoglobin, its yellow color being due to a pigment variously called lutein (Thudichum), hydrobilirubin (Maly), and choletilin (MacMunn). The readiness with which the red corpuscles may be partially dissolved in the plasma varies greatly in different individuals. In some this may be accomplished by ligaturing one of the fingers and immersing it in ice-water; after which, a drop of blood taken from the finger-pulp will show decolorized corpuscles floating in a pink plasma. This experiment was repeatedly performed by Ehrlich upon a patient possessed of this abnormal susceptibility to the action of cold. In such an individual, a prolonged general exposure to cold—no greater than that to which all active persons are liable in the winter season—will cause so great a separation of coloring matter from the corpuscles that it makes its appearance in the urine. Hence the term *winter hæmaturia*, incorrectly applied to these cases. Hæmaturia—the presence of red blood-corpuscles in the urine—cannot occur without inflammation of some portion of the genito-urinary tract, or rupture of some part of its vascular apparatus; and in hæmoglobinuria there is neither. Excessive heat will also produce hæmoglobinuria, which has been often observed to follow extensive burns of the surface. Among the other numerous agents capable of producing this symptom may be mentioned certain edible fungi (morchella and helvella esculenta); potassium chlorate carelessly administered; inhalation of arseniuretted hydrogen; transfusion of alien blood; inunction of pyrogallic acid and naphthol; and the transfusion or hypodermic injection of glycerin, toluylendiamin, anilin, and dimethylanilin. Poisoning by phosphorus will also give rise to it. Among the diseases attended with this symptom are scorbutus, purpura, pyæmia, typhus, and, above all, the malarial fevers. The earliest reported cases of hæmoglobinuria —they were thought to be cases of *hæmaturia*—were due to malarial poisoning. Harley was the first to recognize the true nature of this symptom. In the Medico-Chirurgical Transactions, vol. xlviii. p. 161, he points out that it is the "hæmatoglobulin itself" which is excreted by the kidneys.

At the present time there is still a great deal of confusion and ignorance upon this subject; and it is the knowledge of this —a knowledge forced upon the writer by glaring misstatements in medical journals —that has led to the publication of this article.

It might be supposed that they who have the greatest opportunities for observing a disease would make the most valuable contributions to its pathology; but this is not the case. The reverse seems rather to obtain; for where a disease is rare, it attracts to its study those who are most capable of explaining the relations between its symptoms and lesions,—its pathology in the widest sense. The latter remarks are due to the fact that very little has been done by the physicians of warm latitudes to elucidate the pathology of malarial hæmoglobinuria, which is so common among them. A notable exception is Dr. Carl Heinemann, of Vera Cruz, who made some

valuable observations in the case of a boy æt. 15, which are recorded in *Virchow's Archiv*, Bd. cii. The rule holds good, however, that our principal knowledge of hæmoglobinuria has been contributed by men inhabiting countries in which this affection is rare.

Among the misstatements above referred to are the following. A practitioner, in reporting a well-marked case of malarial hæmoglobinuria, says that he begins to feel hope of a favorable termination as soon as the bowels begin to discharge black bile. The black, tar-like "bile" is undoubtedly altered hæmoglobin, which often appears in this situation, and even in the vagina, as was observed by Dr. Dreschfeld and Mr. Stocks, of Manchester, in a case of poisoning with potassium chlorate.* Another writer states, with reference to malarial hæmoglobinuria, "The urine is not bloody, but contains cholesterine. Dip a white cloth in it, you find the yellow copperas dye." What this means I have not the slightest idea. It sounds like the wanderings of a man who had been dreaming about the subject, or of one who had been made mad by much learning in connection with it. If this explanation is incorrect, it certainly shows how completely the subject is misunderstood by those whose opportunities for studying it are greatest.

In the opening sentence of this article it is stated that hæmoglobinuria is the most emphatic expression of hæmoglobinæmia. The adjective was used advisedly; for just as sugar may be present in the blood in unusual amount without glycosuria necessarily resulting, so hæmoglobinæmia may exist without hæmoglobinuria. It is only when the capacity of the spleen and liver for removing the excess of hæmoglobin is exhausted that this substance appears in the urine. It is probable that improved methods of research will lead to the detection of hæmoglobinæmia in many diseases in which its presence is not even suspected. Litten, in view of the well-known fact that the marrow is changed from yellow to red in certain cases of pernicious anæmia,—a disease in which increased destruction of red corpuscles is generally supposed to exist, although never positively demonstrated,—has suggested a spectroscopic examination of the blood-serum in this disease. The suggestion is a good one, and should be extended to all varieties of anæmia.

The diagnosis of hæmoglobinuria is made with the spectroscope and certain chemical tests,—namely, Heller's and the guaiacum test. The negative evidence furnished by the microscope—absence of red corpuscles—is not sufficient. It has been stated that the albumen of hæmoglobinuria differs from ordinary albumen in that it does not sink to the bottom of the urine, but "floats on the surface of the liquid in a long, ropy strand."

In the number of this journal for April 3, 1886, I endeavored to prove, and I think successfully, that the blood of pernicious anæmia affords an instance of the law of reversion. For the facts upon which this theory was based the inquirer is referred to the source mentioned. I stated that, so far as I knew, there was no other instance of genuine *tissue-reversion*, using the word "reversion" in its strict evolutionary sense, which is that the "adult organism possesses a character which is never assumed by the normal embryo, but which resembles an adult *ancestral* form to a degree which varies with the extent to which development has proceeded along the obsolete track." In diseases attended with hæmoglobinæmia, the blood of man comes to resemble that of the earthworm, showing that, in this affection at least, certain Biblical comparisons rest upon a biological foundation. The earthworm has red blood, but the plasma contains the hæmoglobin, while the corpuscles themselves are colorless.

The disorder produced by "matter out of place" in the inorganic world finds more than one parallel in the organic; but none more striking than that furnished by the affection under consideration. The substance hæmoglobin, which we are accustomed, and justly, to consider the most vital, is no sooner separated from the red corpuscles than it becomes a foreign body, to be got rid of as rapidly as possible. This process of excretion is at times extremely irritating to the organs concerned in it, and in the severest cases the hæmoglobin may block up the uriniferous tubules to such an extent as to cause complete anuria. The true meaning of the term "foreign body" is thus seen to signify not so much a body foreign to the organism as one out of place within it.

* Trans. International Medical Congress, London, 1881.

The jaundice which so frequently occurs in connection with hæmoglobinuria is undoubtedly of the hæmatogenous variety.

FREDERICK P. HENRY, M.D.
721 PINE STREET, PHILADELPHIA.

NOTES FROM SPECIAL CORRESPONDENTS.

BOSTON.

THE educational season opened in this city about the 1st of October, both for the student and the practitioner of medicine. The classes at the Harvard Medical School remain in general about as they have averaged heretofore, but the "fourth year" gives evidence of increased popularity, inasmuch as some twenty men have enrolled themselves in it. This additional year of study gives no special advantage in the diploma which it bestows, but it offers clinical facilities in connection with most of the medical and surgical specialties analogous to those given in the ordinary polyclinics and post-graduate schools. Many students make this year cover also in part an externe service in connection with one of the hospitals.

Dr. R. T. Edes, of this city, who has just removed to Washington, resigned the chair of Clinical Medicine in the Harvard School. At his departure he was tendered a banquet by his colleagues of the medical faculty, by the staff of the City Hospital, and by the members of a small local medical club of which he had long been a member. The speaking was very flattering to the professional character of Dr. Edes. The important chair which he vacated in the University has not yet been filled.

The first meeting of the Section of the Suffolk District Medical Society in Clinical Medicine, Pathology, and Hygiene was held October 13, and was devoted to a consideration of the problem of water-filterage. An invitation to any of the general public interested had been given, and the result was an unusually full meeting. The discussion was opened by Professor W. T. Sedgwick, of the Institute of Technology, with an interesting paper. He took the ground that all the filters in use were merely strainers, removing more or less completely suspended matters but not bacteria. The "micro-membrane filter" was especially described, in which the filtering-material is asbestos in a very minute state of subdivision. Experiments showed that it completely decolorized a solution of ultramarine, a severe test for the decolorizing power of any filter, but there was no sufficient evidence that bacteria could be arrested by it; nor, in the opinion of Professor Sedgwick, was it necessary for the public health in the present state of the Boston water-supply that micro-organisms should be removed, even if that were possible. The inventors of various filters were given an opportunity to explain the features of their respective articles. Dr. Ernst, who had made some experiments on the sterilizing power of various filters in Koch's laboratory in Berlin, said that the conclusion there arrived at was that one filter only—viz., that of Chamberlin, of Paris, consisting of unglazed porcelain—possessed the power of arresting the transit of bacteria. After a continuous use of three weeks no micro-organisms were found to pass it. Other devices, such as animal charcoal, would arrest bacteria for a day or two, but after that they grew through the filter, and the total amount of these organisms in the effluent was greater than in water that had not been passed through a filter at all.

Since my last letter Dr. Charles D. Homans, a late president of the Massachusetts Medical Society, and a widely-honored and respected man and physician, has died. As the senior surgeon of the City Hospital, as president of the Humane Society, and in many other relations, he leaves a place difficult to be filled.

The trustees of Perkins Institution for the Blind, one of the most useful of our local charities, held their annual meeting on the 13th instant. There are at present one hundred and forty-six pupils and thirty-four blind teachers and other employés. A kindergarten for the blind has during the past year been the beneficiary by several charitable concerts and other entertainments in this city, at two or more of which the "Autocrat of the Breakfast-Table" read some of his admirable poems. A sufficient sum has been raised to erect a building for the use of the kindergarten, which will be completed in about three months.

At this meeting some very interesting exhibitions of the modes of study were given. Especial interest was shown in the method of teaching geometry and geography. The maps are of course in relief, and the pupils in describing them, and even in making them (in clay), appear to have some advantages in the conception which they gain of some of the physical characters of the countries over children who study geography simply from the ordinary maps.

One case of smallpox, the first in a considerable time, appeared here last week. It was a serious case, but was, as usual, promptly removed to the hospital.

The trustees of the City Hospital voted—October 14—adversely upon a petition for the establishment of homœopathic practice in the hospital, and favorably upon a petition to allow female medical students to be present at certain surgical operations in the amphitheatre, "with the proviso that the attending surgeon or physician may on any occasion reserve such cases as he deems improper for consideration in the presence of students of

both sexes to the end of the lecture, and before proceeding with them require the withdrawal of all male or female students, as the case may be."

As the result of investigations made by the trustees into the usage of other hospitals regarding the admission of women, the following facts are given:

Total number of hospitals which admit students to surgical operations	76
Number of hospitals which admit female students to surgical operations	46
Number of hospitals which do not admit female students to surgical operations	25
Number of hospitals which have no rule upon the subject and to which no female students have applied for admission	5

C. F. W.

October 15, 1886.

PROCEEDINGS OF SOCIETIES.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

IN 1884, the American Public Health Association, acting upon a suggestion made by the *Sanitary News*, extended an invitation to the sanitarians of the Dominion of Canada to join the Association. The invitation was heartily accepted, and Drs. C. W. Covernton and P. H. Bryce, President and Secretary respectively of the Provincial Board of Health of Ontario, attended the meeting at St. Louis as the representatives of the Dominion and Provincial governments. At the meeting in Washington last year Dr. Covernton was elected first vice-president of the Association, and it was decided to hold the meeting of the current year in the capital of Upper Canada.

The attendance at the meeting was somewhat less than usual, owing probably to the great distance of the meeting-place from the States where most of the active members of the Association live. There were, however, present members from California, Louisiana, Georgia, South Carolina, New Brunswick, Manitoba, Minnesota, and nearly all the intervening States. Dr. Russell, the Health Officer of Glasgow, Scotland, was also present, and was made an honorary member of the Association.

The meeting was called to order at ten o'clock on Tuesday, October 5, and after routine reports a paper by Dr. George Baird, of Wheeling, West Virginia, was read by Dr. James E. Reeves, on the "Destruction of Night-Soil and Garbage by Fire." The paper contained an account of practical experiments made in Wheeling to determine the best method of cremating the refuse of cities. It will be published in full in the *Times*.

The pollution of the water-supply and the sewerage of Toronto were very fully discussed in several papers, in which, however, very little new was developed.

*

The annual address of the President, Dr. Henry P. Walcott, of Massachusetts, was an eloquent and scholarly discourse on the present necessities of sanitary science, and how they were to be provided for. There was enough to do, he said, in the directions where both science and experience have arrived at some definite conclusions; but advance in any quarter must necessarily be slow, made under the guidance of systematic experiments and observations controlled by scientific methods, and not in the pursuit of the speculations of theorizers. The principal object of scientific inquiry in preventive medicine during the past year has been, he said, as in the preceding year, the study of the infectious diseases and the micro-organisms associated with them. He went on to review what has been done and what is being done in the study of such diseases as cholera, smallpox, yellow fever, scarlet fever, rabies, and trichinosis. All these were of too much importance to be neglected by the guardians of the public health. To meet the present needs of sanitary science, the President advocated the undertaking by the general government of scientific investigations of diseases which are so general in their distribution that the whole country is affected by them, or of such character that the satisfactory inquiry into them would involve expenditures too great for the meagre appropriations of State and local boards of health. Some of the investigations carried on under the direction of the National Board of Health of the United States were of the highest scientific merit, and had an acknowledged authority everywhere. The public burden from the victims of the misuse of alcohol was becoming each day greater and more intolerable. Public measures of repression had thus far been of so little avail that it seemed to him fitting, on an occasion like that and with such an audience, to invoke for this most important subject the influence and teachings of the profession so largely represented there, and of all those whose business it was to help their fellow-men to healthy minds in healthy bodies. The President enumerated the matters affecting the public health in which a general government can exercise a beneficial control. He noted the advance which has been made in State medicine in Canada since the formation of the Ontario Board of Health in 1882. In regard to quarantine he said, "The recently published quarantine regulations of the Dominion are quite sufficient for your protection and for ours, if they are rigidly enforced. The vast sanitary importance of this highway to the West—the road by which cholera has once at least entered the country—cannot be overstated." He had noticed that there was one thing allowed here in Canada which experience, in his own State at least, had condemned: the presence of municipal councillors on local boards of health. He concluded

by calling attention to the great work which could be done by intelligent and fearless health authorities.

Dr. Salmon, of the Bureau of Animal Industry at Washington, read an interesting paper upon "Recent Investigations upon Hog-Cholera." He said recent discoveries showed that the disease was caused by bacteria. Sterilized culture-liquid used as an inoculant was found to protect pigeons against the living germs. The experiment had not been yet carried out to a conclusion in regard to protecting hogs. The microbes multiplied with extraordinary rapidity in water: about eightfold in twenty-four hours. This experiment showed these germs had power of multiplying in ordinary drinking-water, such as is taken from our rivers and streams. A solution of mercuric iodide—proportion one to two millions—was found to destroy the germs. The question therefore suggested itself whether the fluids and tissues of hogs could not be so impregnated with this disinfectant as to render them absolute proof against the bacteria.

The Committee on Disinfectants reported that they had prepared descriptions, illustrated by diagrams, of all the different forms of apparatus used for disinfection by heat. The conclusions of the committee are as follows:

Apparatus for disinfection by heat may be divided into three classes: 1, those in which dry hot air is employed; 2, those in which moist hot air is used; and, 3, those in which steam is the disinfecting agent.

Dry hot air cannot be relied upon for disinfection when great penetrating power is required, as in disinfecting mattresses, feather-beds, and thick bundles of clothing or of cotton and woollen goods. Besides, dry hot air of a sufficiently high temperature to act as an efficient disinfectant often permanently injures textile fabrics and other objects requiring disinfection. The very recent investigations of Dr. Parsons and of Professor Max Wolff, of Berlin, fully attest the conclusions of the committee upon this point.

Notwithstanding these objections, dry hot air may probably often be used as a disinfectant with good results if the above-mentioned limitations be borne in mind. In no event, however, can dry heat be expected to prove an efficient disinfectant unless a temperature of above 110° C. (230° F.) has been maintained for upward of two hours.

In none of the various apparatuses designed for disinfection with dry hot air has a uniform distribution of heat in the disinfection-chamber been attained. In order to obviate this difficulty, some inventors and experimenters have rendered the hot air humid either by evaporating water in the chamber or by injecting steam into the same. By this means the distribution of heat is rendered more even, and its penetrating power is said to be increased.

In using hot-air apparatus, the fuel employed is of some importance. By the use of gas the heat can be maintained more equably than when coal, coke, or wood is used. The feeding of the furnace, when the latter forms of fuel are employed, allows a certain amount of cooling off, and hence a corresponding loss of heating-time. When the heat is furnished by a current of steam circulating through a steam-pipe properly disposed in the disinfecting-chamber, considerable uniformity in temperature can be maintained.

Apparatuses for disinfection by steam are of two sorts: those in which the steam passes through the disinfecting chamber without compression, and those in which it is confined by pressure. In the former the vapor is sometimes superheated by a secondary heating-apparatus, and this is probably equally efficient as steam under pressure. The experiments of Professor Wolff have shown that, with an apparatus in which the steam is not under pressure, an exposure of at least one hour is requisite for thorough disinfection.

The committee expressed its conviction, based upon the practical experience of some of its members, that the use of steam, especially when superheated or under pressure, is the most efficient agent for the destruction of all sorts of infectious material.

The Conference of State Boards of Health, which met at the same time as the Association, discussed the problem of "Inter-State Notification of Diseases," and adopted the following resolutions:

"1. *Whereas*, It is necessary for the protection and preservation of the public health that prompt information should be given of the existence of cholera, yellow fever, and smallpox, be it resolved that it is the sense of the National Conference of State Boards of Health that it is the duty of each State, provincial, and local Board of Health in any locality in which said diseases may at any time occur, to immediately furnish information of the existence of such diseases to Boards of Health of neighboring and provincial States and to the local board in such States as have no State Boards.

"2. *Resolved*, That upon rumor or report of the existence of pestilential disease, and positive, definite information thereon not being obtainable from the proper health authorities, this Conference recommend that the health officials of one State shall be privileged and justified to go into another State for the purpose of investigating and establishing the truth or falsity of such reports.

"3. *Resolved*, That, whenever practicable, the investigations made under the preceding section shall be done with the co-operation of the State or local health authorities.

"4. Any case which presents symptoms seriously suspicious of one of the aforenamed diseases shall be treated as suspicious and reported as provided for in cases announced as actual.

"5. Any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not pestilential shall be reported as suspicious.

"6. Any case respecting which efforts are made to conceal its existence, full history, and true nature, shall be deemed suspicious and so acted upon.

"7. *Resolved*, That in accordance with the provisions of the foregoing resolutions, the Boards of Health of the United States and Canada represented at this Conference do pledge themselves to an interchange of information as herein provided."

These resolutions were also approved by the Association.

While the scientific work of the Association at the meeting just closed is hardly up to the average of previous meetings, the social entertainments were profuse and of the most enjoyable nature. In fact, the courtesies of the hospitable citizens of Toronto were so generously tendered as to interfere somewhat with the proper work of the Association. A large number of the members brought their wives and other feminine relatives, and the ladies of Toronto successfully vied with each other in making them feel at home. Although the Canadians live in a cold country, we have found that they have warm hearts.

The following officers were elected for the ensuing year: Major George M. Sternberg, Surgeon U.S.A., President; Vice-Presidents, Drs. C. N. Hewitt, of Minnesota, and C. A. Lindsley, of Connecticut; Dr. J. Berrien Lindsley, of Tennessee, and Dr. Irving A. Watson were re-elected as Treasurer and Secretary respectively. The Executive Committee consists of Drs. Henry B. Baker, of Michigan, Joseph Holt, of Louisiana, Hosmer A. Johnson, of Illinois, F. Montizambert, of Canada, George H. Rohé, of Maryland, and Colonel D. P. Hadden, of Tennessee.

The next meeting of the Association will be held in Memphis in November, 1887.

G. H. R.

Toronto, Canada, October 8, 1886.

PHILADELPHIA ACADEMY OF SURGERY.

A MEETING of the Philadelphia Academy of Surgery was held October 4, 1886, Dr. Thomas G. Morton in the chair.

Dr. James Collins exhibited a patient suffering with

AN ENORMOUS TUMOR OF THE RIGHT UPPER JAW,

and said: I wish to call the attention of the Fellows to this case. The patient, a lady 45 years of age, noticed, five years ago, frequent bleeding of the nose. There was also some difficulty in passing the collections of mucus, etc. She was treated in various ways, but soon a swelling made its appearance below the right eye. The tumor gradually increased in size, and two years ago my attention was called to it. There was then a large prominence, suggesting a tumor of the nostril. There is now a large tumor, involving the right side of the face, filling up one side of the nostril, and pressing upward so as to cause protrusion of the eyeball. The sight of the right eye has been lost for the past two years, and she has almost entirely lost hearing on the right side. When pressed upon, the tumor is soft and elastic, feeling like soft bone. Just inside the mouth is an opening which is disposed to bleed readily. There is not much pain connected with the growth, which in the past six months has developed rapidly. When I saw the case two years ago, the question of operation was considered. The friends wished positive assurance that the patient would be benefited; but this we were unable to give, and the operation was deferred. Within the last few months there has been a decided failure of general health and strength. By passing a finger into the antrum through the opening in the mouth, that cavity is found to be free and smooth. The growth seems to be a gradual enlargement of the bone itself rather than the result of pressure from within.

I should like to have an expression of opinion in reference to the correctness of our judgment in deciding not to operate two years ago. I would also request suggestions as to what should be done in the case further.

Dr. J. Ewing Mears: The appearance of this case is almost identical with that of one I had under my care in 1877, and upon which I operated. The history and appearance of this case would indicate that it is one of encephaloid tumor springing from the antrum, and that the pressure has produced absorption of the wall of the antrum. If the tumor were removed, there would be found a large opening, extending perhaps to the base of the cranial cavity. In the case on which I operated the tumor projected into the frontal sinuses, and had destroyed by absorption the anterior and posterior walls of the antrum. It also extended to the base of the cranium, so that, when I finished, I had my finger on the sphenoid bone and even in the sphenoidal cells. The patient lived ten days after the operation. I was called out of the city shortly after the operation, and when I returned I learned that the patient had died, it was said from pneumonia.

Dr. Charles B. Nancrede: I notice that the patient can move the eyeball. The portion of bone to which the muscles are attached must therefore be carried forward. The protrusion seems to be due not so much to bulging of the eyeball as to advancement of the entire cavity.

Dr. Mears: In the case to which I have referred, the eyeball was thrust out of its cavity, but all the motions were preserved. A tumor forcing its way into the orbit causes elonga-

tion of the muscular as well as of other tissues. I do not think it necessary that the point of origin of the muscles should be advanced.

I think that it is the judgment of surgeons who have much to do with jaw-surgery that in carcinoma of the upper jaw, including scirrhus and encephaloid, no operation should be performed; that in sarcoma, especially in children and young persons, an operation is frequently followed by success. In true carcinoma, operation is, as a rule, followed by recurrence. With regard to operation in this case at this time, I think that it could be performed, but the patient would probably not survive the operation long, even if she survived the shock of the operation. The return of the disease would probably be very rapid, as it would be practically impossible to remove all the disease. While the hemorrhage which attends removal of the upper jaw looks very formidable, I have experienced no trouble in controlling it. Pressure is usually sufficient, but in one or two instances ligature was required. I cannot recall a case of fatal hemorrhage following extraction of the upper jaw. Six years ago I removed the upper jaw of a girl eleven years of age. The tumor was examined by Professor S. W. Gross and found to be a spindle-cell sarcoma. There has been no return of the disease.

Dr. J. H. Packard: In 1877 I had a patient with a tumor of the orbit which appeared to originate from a clot of blood effused in a severe labor many years before. I have published a report of this case, with a sketch showing the appearance before and after operation. The eyeball was forced down on the cheek. I removed the tumor without difficulty and replaced the eye. I have seen the patient repeatedly since then, and everything has gone back to the normal condition. It seemed as though the muscles which had been stretched had recovered their tone. The sight had not been impaired by the tumor.

The origin of the deafness in the case presented to-night seems to be obscure, for there are no other symptoms indicating pressure at the base of the brain.

An operation in this case, it seems to me, would be one of great gravity. If the patient were suffering severe pain, an operation would be more positively indicated than it is under existing circumstances. The dangers of the operation would be very great, and it is possible that there would be hemorrhage which could not be controlled except with the cautery, and perhaps it could not be reached with this instrument. If the patient were willing to risk the operation and all its dangers, it might go far towards inducing the surgeon to operate; but an operation should not be urged in such a case. I agree with Dr. Mears as to the possibility of controlling the hemorrhage. I have never seen death result from hemorrhage in the removal of the upper jaw; but I have always been obliged to use the cautery. In this case there has been a change in the vessels. The point of hemorrhage may be removed from the vision, and it may be difficult to reach the vessels to apply the cautery. In the cases which I have seen, the hemorrhage has really been formidable. I have seen greater hemorrhage and more difficulty in arresting it in the removal of tumors of the jaw than in any other form of growth. I should not undertake such an operation without having the cautery at hand.

Dr. W. Joseph Hearn: The question of operation depends much upon the diagnosis. If this is an encephaloid growth, the operation is hardly justifiable; if it is a sarcoma (probably spindle-celled), I think that two years ago an operation would have been justifiable. In my service with Professor Gross I assisted him in several operations on what we then called recurrent fibroid tumors of the jaw. In one of these cases recurrence has not taken place. I think that at this time it would not be proper to perform an operation in this case.

Dr. Charles B. Nancrede: From the cases which I have seen, I would agree with Dr. Packard that the hemorrhage is apt to be severe. In some of the cases nothing but the repeated applications of the actual cautery checked it. In one case which I saw operated on, while the patient did not die on the table, he did practically die of hemorrhage.

Dr. Thomas G. Morton presented a patient who had made rapid and very satisfactory recovery from a

COMPOUND COMMINUTED FRACTURE OF THE CRANIUM.

This man, aged 47 years, was admitted to the Pennsylvania Hospital on September 7, with a compound, comminuted, depressed fracture of the upper portion of the right frontal bone. The injury was produced by a monkey-wrench falling from the fifth story of a building. The patient was admitted about two and one-half hours after the reception of the injury. I bring the case before you as an instance of immediate and primary union, with perfect recovery from the date of the first dressing. The dressing was not removed until the fourteenth day, although the patient was about the ward on the fourth day. The crown of the trephine used was as large as a five-cent piece. About twenty fragments were removed, and a large piece of the internal plate taken away. The opening left was as large as a quarter of a dollar.

The head was carefully shaved, and then washed with the bichloride solution (one to two thousand). The instruments were, as usual, boiled previous to operation and placed in a three-per-cent. solution of carbolic acid. After the operation the wound was thoroughly washed, first with a one-to-one-thousand solution and subsequently with a one-to-five-thou-

sand solution of the bichloride. The edges were carefully approximated, and two fine threads of catgut laid across the wound for drainage. The surface was then dusted with iodoform and covered with gauze soaked in the bichloride solution and dusted with the iodoform. Over this was placed a piece of Lister's gauze wet with a one-to-two-thousand solution, and secured with a bandage treated in the same way. A cotton dressing was then placed over this. The temperature did not go above 99°. When the bandage was removed the strands of catgut had disappeared.

I have brought the patient before you not only to show what I consider to be a remarkable instance of immediate union after such an injury, but also to suggest that if we can obtain through careful antisepsis primary union in compound comminuted fractures of the skull, we shall in large measure avoid the occurrence of fungus cerebri, which in reality is a low grade of inflammatory action.

Dr. Charles B. Nancrede: It is impossible to have fungus cerebri unless there is intracranial suppuration, with an increase of intracranial tension and softening of the brain-substance. If, as sometimes happens, the inflammation extends from without inward as a septic process, primary union of the wound will unquestionably stop it. If the primary injury is sufficient to produce the requisite amount of intracranial inflammation, fungus cerebri will occur in spite of the most careful treatment of the wound. Cases in which the projection is nothing more than a mass of granulations springing from the dura mater differ from true fungus cerebri, which contains brain-tissue. These latter cases are usually due to the original injury, and not to the inflammation from without. The hernia cerebri may even occur after the external wound has closed. Such a case is reported in the International Encyclopædia of Surgery. There are several cases on record where the destruction of bone, produced probably by a gumma, has resulted in hernia cerebri.

Two of my last three cases of hernia cerebri have recovered. I have prepared some statistics as to the mortality of this affection, showing that it is not so great as is generally supposed. Almost all the cases that have recovered have been treated practically on the let-alone plan. That was the method pursued in the cases under my care. I applied gentle pressure, antiseptic dressings, and mild astringents. Both of these patients have since had epilepsy. As far as I have followed out the microscopical pathology of this condition, the only barrier to further protrusion is the presence of the granulations, and every time they are removed you remove the barrier which nature has provided. The less these granulations are meddled with, the greater will be the chance of recovery.

Dr. Thomas G. Morton: I can perceive that there might be cases in which fungus cerebri occurred in the manner described; but I think by closing the wound immediately and removing all sources of irritation, fungus cerebri may be avoided in cases where it would otherwise have occurred. Even if the dura mater were injured, I think that under this method of treatment fungus cerebri would be less likely to develop.

I have seen a number of these cases. One case in a child six years of age, which I treated one year ago with the ligature, recovered. The ligature was applied every other day. In this case the dura mater was injured and considerable brain-substance was lost. The mental power was not impaired by the accident.

Dr. Mears: Since 1876, when I began to use the modified antiseptic dressing in St. Mary's Hospital, I have not seen a case of hernia cerebri, although I have had some eight or ten cases of compound comminuted fracture of the cranial walls, with injury to the dura mater and to the brain-substance. I do not know whether this is to be attributed to the use of antiseptics or whether it is simply a coincidence. In one case where the fracture was produced by the kick of a horse, I removed a piece of the inner table which was larger than a silver dollar. In order to get it through the opening in the external table, I was obliged to cut it with pliers and remove it piecemeal.

Dr. J. H. Brinton: During the past few years I have seen several cases of hernia cerebri. The most marked case was in an officer, in which the parietal bone of the right side was injured by a gunshot. The hernia was marked, and extended one and a half inches in height. Disintegration of the mass took place, and finally extended to the base of the projection, and I shaved it off, and the patient made a good recovery. There was no marked mental disturbance.

Adjourned.

NEW YORK ACADEMY OF MEDICINE.

AT a stated meeting of the Academy, October 7, 1886, the President, A. JACOBI, M.D., in the chair, a paper entitled

SOME PHASES OF CEREBRAL SYPHILIS

was read by JULIUS ALTHAUS, M.D., M.R.C.P., Corresponding Fellow of the Academy.

The author, after some introductory remarks, first spoke of the history of cerebral syphilis, and said that the disease had been only imperfectly recognized until after the middle of the nineteenth century, when a new era in the history of the subject began in the great impetus given the study of its pathological anatomy. It was then demonstrated that syphilis of the brain was not an inflammation, but that it bore throughout the character of a neoplasm. Syphiloma and arterial thrombosis cover, indeed, the immense ma-

jority of cases of cerebral syphilis met with in practice. A disappointing feature of Virchow's work is that he does not point out clearly the connection between the clinical signs and the pathological lesions of cerebral syphilis, and he appears to be only moderately acquainted with the modern doctrines of cerebral localization.

Coming more particularly to the subject of his paper, the author said that time would allow only of his considering syphilitic coma and syphilitic hemiplegia. That coma coming on more or less suddenly in an apparently healthy man, but one who had had unmistakable symptoms of venereal disease, might be a manifestation of the latter was a fact not generally known to the profession. Many causes of coma are mentioned in the text-books, while syphilis is not referred to; Fournier is almost the only author who has alluded to it, and he only briefly. But a knowledge of syphilitic coma is of great practical importance, inasmuch as it requires an entirely different treatment from that of other forms of coma, and an incorrect diagnosis is likely to seal the fate of the patient.

Dr. Althaus had seen, altogether, eight unmistakable cases of syphilitic coma, all in males between twenty-five and forty-two years of age. In every one there was a definite history of primary and secondary syphilis. In two cases no other cerebral symptoms occurred before the coma; the others suffered with giddiness, epileptiform convulsions, and transient loss of power in the limbs. Among the exciting causes of the attack he had noticed overwork, anxiety, trouble, sexual excess, and alcoholic habits. In two cases no exciting cause was ascertained; six were professional men; two were without regular occupation.

The symptoms were classified as: first, premonitory signs; second, symptoms of the initial stage; and, third, the symptoms of the final stage of coma.

He had noticed the following premonitory signs: a feeling of confusion, black specks before the eyes, sudden loss of sight for a short time, numbness in the limbs, some loss of mental power. In six cases there were such symptoms for a few hours or a day or two before the attack. The initial stage of coma set in during sleep; the patient was found in the morning on his back, apparently quite unconscious; he did not moan, nor throw himself back, nor put the hands to the head; his expression was blank, surface generally pale; sometimes he could be roused by shouting to him; he appeared to recognize the face of a friend better than that of a stranger; to loud interrogatories he might answer that he was blind, or only respond with a movement of the lips; the tongue was dry: dorsum covered with fur, except a few red papillæ: protruded slowly, but not deviated to one side; when put into his mouth, he generally succeeded in swallowing a small quantity of fluid; the eyelids were closed; on opening them the eyeballs seemed deeply retracted into the orbit, one more so than the other; their axes appeared to diverge, the greater the coma the greater the divergence; the pupils were small, insensitive to light; ophthalmoscopic examination at first was precluded, but when practised it revealed nothing unusual; the reflex irritability of the conjunctivæ was blunted and gone; the breath was offensive; the muscles were relaxed, and the body and limbs retained any position given them; the arms and legs offered no resistance, and fell heavily when dropped; there was no difference at all between the two sides of the body; there was no appearance of hemiplegia, rigidity, or tremor. In all the cases the sensibility and reflex excitability were greatly diminished or absent; the reflexes were wanting or were elicited with considerable difficulty. There was, either from the first or very soon, incontinence of the bowels and bladder, especially of the latter; occasionally there was constipation. The pulse was habitually slow, beating at the rate of 40, 50, or 60; its quality varied in different cases; it might be hard and wiry, or tolerably full, or small and feeble. Respiration was slow and shallow, the average rate being 8 or 10. The temperature was below the average, from 96° to 97° F. In two cases there was an eruption of herpes on the face; the skin was generally dry.

What, he asked, was the condition of the brain? It was evidently a complex one, for, while we have on the one hand the symptoms of paralysis, there are on the other hand symptoms of irritation of the nervous centres. The loss of consciousness and voluntary motion and sensation showed that the functions of the cineritious substance of the hemispheres, notably of the temporal and frontal lobes and frontal convolutions, were in a state of abeyance, while the state of the pulse, respiration, and temperature showed a condition of irritation in the medulla oblongata and pons Varolii.

The initial stage of syphilitic coma lasted in general from two to five days, and was followed by recovery or merged into the final stage, leading to death. In the former case the patient gradually began to show signs of returning consciousness; in ten days or a fortnight he might apparently be well. In other cases recovery was slower and less perfect; the speech remained indistinct and halting, the memory was weak, the patient did not take much interest in his affairs nor show much affection for his family: at times he appeared to realize his condition acutely, and burst out crying. Eventually, however, even in these least favorable cases the brain-power might be more or less restored, showing but little deterioration as compared with what it was previous to the attack. This is

the bright side of the picture; and as recovery takes place, the result of energetic antisyphilitic treatment, the physician may justly take to himself credit for having benefited the patient.

But there is also a dark side. In the unfavorable cases the patient gradually sinks into the final stage of syphilitic coma in a few days, characterized by intensification of the symptoms of unconsciousness, loss of voluntary power, sensation, and reflex excitability, while the signs of irritation of the pons and bulb change to those of a paralytic state of those organs; the face becomes livid and cyanosed, the conjunctivæ injected, insensitive to touch, the jaws fall apart, the power of swallowing is lost, there is excessive secretion of mucus or dryness of the lips and mouth, the surface of the body is bathed in clammy sweat, the pulse becomes small, feeble, quick, the respiration now becomes accelerated, perhaps stertorous, passing into Cheyne-Stokes type; hypostatic pneumonia may develop; the temperature rises to 104° to 108° F., the pupils become enlarged, and finally death occurs.

Of the eight cases of syphilitic coma which the author had seen, six ended in recovery, two in death in the first attack. In three of those which recovered from the first attack a relapse took place after some time, and one of them eventually died after having survived five such attacks in three years. He could not obtain an autopsy in either of the fatal cases.

Reasoning from analogy, however, it seemed to Dr. Althaus that the clinical history would warrant the inference that in these cases we have to do with an affection of an important cerebral artery which becomes gradually occluded by the syphilitic deposit, and that probably the vessel principally implicated is the basilar artery, which supplies the vitally most important parts of the brain. Sudden occlusion of this artery by inflammation leads rapidly to a fatal result, the principal symptom being profound coma from the beginning of the illness; but when a specific deposit takes place in the basilar artery, it seems that much more time is required to produce occlusion. But while this seemed to him to be the explanation of syphilitic coma, he admitted that the view wanted the proof of ocular inspection.

The author then took up the subject of diagnosis, and said that the cases which are most likely to be confounded with syphilitic coma are those in which hemorrhage takes place into the pons, also some cases of opium-poisoning. Other conditions he mentioned were hystero-epilepsy, alcoholic coma, uræmic coma, and diabetic coma. In opium-coma the pupils are extremely contracted; not so in syphilitic coma. In the former itching of the skin and suppression of urine occur; in alcoholic coma there is the odor of alcohol in the urine, and the pupil is enlarged. The diagnosis is not difficult in uræmic coma if the history is known; there are attacks and remissions, and not the dead-level unconsciousness seen in syphilitic coma. Acetone in the breath and urine accompanies one form of diabetic coma.

The prognosis of syphilitic coma is always grave. The disease shows that the poison of syphilis has insinuated itself into the cerebral arteries, and that eventually there will very likely be a return of the attack. The prognosis of an individual attack is on the whole not very unfavorable, more especially if the patient will accept specific treatment at the outset.

The treatment is partly symptomatic and partly antisyphilitic. The patient should receive at regular intervals easily-digested substances. If he appear to be in imminent danger of death, hypodermic injections of ether may sometimes turn the balance in his favor. Blisters to the back of the neck or on the forehead sometimes appeared to yield beneficial results. The douche appeared to do more harm than good. The principal part of the treatment is the specific, and it consists in the administration of mercury, either by inunction or hypodermic injection. For inunctions the old-fashioned blue ointment is efficient, and he considered a solution of the perchloride the best preparation for hypodermic injection thrown deeply into the substance of the glutei muscles. Other forms of mercury might be employed if preferred.

Some clinical peculiarities of syphilitic hemiplegia as compared with ordinary hemiplegia constituted the subject of the second part of the paper. The immense majority of the patients of this form are males (ninety-five per cent.), while both sexes are about equally represented in ordinary hemiplegia. Most of the patients with syphilitic hemiplegia are young. A peculiar behavior of the deep reflex tendon phenomena has been observed: the occurrence of hemiplegia on one side, with a paralytic affection of the muscles of the eye on the other side, is very significant of syphilis. The author cited cases illustrating different forms of syphilitic hemiplegia, some in which the attack came on suddenly, others in which it came on slowly, etc., and said that while in twenty cases of ordinary hemiplegia taken quite promiscuously all are very much alike, there is hardly a case of syphilitic hemiplegia which exactly resembles another, and it is this extraordinary variety in their clinical aspect which constitutes one of the peculiar features of cases of syphilitic hemiplegia.

Specific treatment failed to cure a very considerable number of cases where there could be no doubt whatever about the specific nature of the complaint. One pathognomonic symptom of syphilitic hemiplegia distinguishing it from ordinary hemiplegia is the presence of excessive exaggeration of the deep-tendon phenomena; the exaggerated response

occurs in the upper as well as the lower extremities.

Regarding treatment, it was a singular fact that while therapeutical results were sometimes very gratifying, they were at other times just the reverse. The cases taught the importance of instituting early specific treatment in all cases of syphilis, in order to avoid secondary lesions, with their attendant symptoms.

Dr. R. W. AMIDON was asked to open the discussion, and said there was one cause of syphilitic coma not mentioned by the author, but which had often forced itself upon his mind,—namely, a weak heart. The occluding disease of the arteries was very well known; but that of itself would hardly account for the very sudden onset of the coma, but when combined with a weak heart the sudden onset of the symptom was well explained.

Dr. A. D. ROCKWELL cited a case of hemiplegia, with facial paralysis and aphasia, which he thought was due to syphilis.

Dr. TAYLOR, speaking of the history of cerebral syphilis, expressed the opinion that the author of the paper had not given sufficient credit to writers previous to the nineteenth century. An admirable digest of the history of syphilitic inflammation of the cerebral arteries would be found in Guy's Hospital Reports for 1879–80. The author's description of syphilitic coma was admirable: he had nothing to add to it. His divisions of hemiplegia were clear and readily understood, but he thought we had the same told us in this country years ago (as early as 1871–72), as the result of the observations of Drs. Van Buren and Keyes, as could be seen in a valuable paper by Dr. Keyes on this subject, in which he spoke of the early age at which syphilitic hemiplegia came on, its gradual development without loss of consciousness, etc.

Dr. Taylor thought there were also other factors in the production of the brain-disease described by the author, the coma, the syphilitic dementia, the general paresis of the insane; such aggravating causes as sexual excess, unnatural sexual habits, and alcoholismus. These three factors go together in the causation of diseases called syphilitic nervous affections.

Dr. L. C. GRAY thought the question as to the exact condition of the brain in syphilitic coma was one on which we yet needed a good deal of light. With regard to the condition of the brain in syphilitic affections, we are generally warranted in attributing them to some precedent arterial trouble; yet in many cases, especially in those in which there is a tendency to coma, the textural changes which take place in the brain are out of all proportion to the changes found in the arteries. He had, last spring, made autopsies upon two cases, neither of which was exactly a typical case of syphilitic coma as described by Dr. Althaus; but in both cases the coma was the main symptom, while the paralytic symptoms appeared later and were entirely secondary. In both he found disease of the cerebral arteries, in one the disease being manifest to the unaided eye as well as under the microscope. But in neither case was the arterial change sufficient to account for the textural disturbance in the brain. In one the textural change was greatly out of proportion to the arterial change; there was very considerable softening, rendering the brain almost pultaceous. In one, besides considerable softening, there were a few patches of meningitis seen in the pia mater; in the other there were not only here and there a few patches of lepto-meningitis, but there were syphilitic gummata forming neoplasms. He therefore thought that the mere theory of some occlusion of the basilar artery was not sufficient to explain the supervention of coma. While a thrombus, an embolus, or gradual proliferation might produce coma, the existence of these conditions in the basilar artery seems unnecessary in order to account for syphilitic coma.

Among the many interesting points in the paper which had attracted his attention was one relating to therapeutics. He had been quite astonished to hear Dr. Althaus speak so favorably of the use of mercury while he had not dwelt to any great extent upon the use of the iodide of potassium, and in this regard he believed the author's views were at variance with those entertained generally by the profession in this country. He had had some experience in the treatment of nervous syphilis, and must say that he had failed to observe any benefit whatever resulting from any mercurial preparation in the treatment of brain-syphilis, whether it came on early or late; but he had found indubitable evidence of the value of the iodide over mercury.

Dr. L. PUTZELL agreed entirely with the reader of the paper regarding therapeutics. He had found that after giving the iodide of potassium, even in large doses, the symptoms did not yield, or yielded very slowly, until mercury was used. Regarding the probable pathology in syphilitic coma, it seemed to him that if the symptoms were purely the result of a thrombus in the basilar artery, there would be more distinct evidence of invasion of the pons and bulbar symptoms. A number of the vessels at the base of the brain being affected, not to the extent of producing occlusion, but causing impaired nutrition, would, he thought, explain the symptoms up to the fatal event, this being probably the direct result of complete occlusion.

AT the Semi-Annual Meeting of the Pathological Society of Philadelphia, held last Wednesday evening, Dr. William Osler read a paper on "Changes in the Blood in Malaria." The meeting was well attended, and a general discussion ensued.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

SPECIAL MEETING, OCTOBER 18, 1886.

The President, DANIEL LEWIS, M.D., in the chair.

JULIUS ALTHAUS, M.D., F.R.C.P., of London, read a paper on

TETANY AND TETANILLA,

in which he said that tetany was only of recent years recognized as a distinct disease, although it probably had existed, as had tetanus, even in ancient times. It was not of frequent occurrence, but owing to its gravity it was important that the physician should be acquainted with its clinical history and treatment. But little was known as yet of its pathology. After a brief review of the history of tetany, in which he gave priority of discovery to Steinheim, Dr. Althaus proceeded to speak of the symptoms, and said that he had seen altogether ten cases of the affection. Four occurred in males, six in females.

Tetany consisted of a succession of attacks of tonic spasm or rigidity of certain groups of muscles, mostly symmetrical, which followed one another at somewhat irregular intervals, there being between the spasms a period of relaxation. There was not loss of consciousness, but there was undue excitability of the motor nerves and muscles.

The chief cause of tetany was certain kinds of irritation coming on in an otherwise enfeebled nervous system. Thus it occurred after diarrhœa, more especially in ill-fed and half-starved children of the poor; also with intestinal worms, or in the nursing woman or at menstruation, after typhoid fever, etc. Another active agent in the production of the complaint was cold; emotional influence was a causative element in two of his cases. Epidemics of tetany had been described, but such cases were probably cases of other diseases, as hysteria or cerebro-spinal meningitis; but several cases of tetany might occur together, due to the exciting factor of cold. Weiss had found four cases of tetany in patients who had had their enlarged thyroid glands extirpated by Billroth, and certain symptoms of tetany had manifested themselves in one patient suffering with myxœdema; it was therefore an interesting question whether there was a more intimate relation between absence or atrophy of the thyroid gland and tetany than had hitherto been assumed.

Tetany had no connection at all with certain occupations, as it occurred in persons following various pursuits. It most frequently occurred between the ages of one and five years, and again between ten and fifteen years; females were more liable to it than males.

A review of the determining causes could not help but lead to the conclusion that a constitutional predisposition must be present in order that cold, diarrhœa, etc., could lead to the outbreak of tetany. In not a single case under his care was there an hereditary history of tetany, but in five out of the ten cases there was such a disease as hysteria, migraine, epilepsy, or chorea in some member of the family. In addition to this, the paternal grandfather of one other patient had died insane, and in another case the parents were first-cousins. It was therefore to be seen that in only three cases out of ten was the family apparently free from a neurotic taint.

The violent symptoms of tetany might develop rapidly or come on gradually, and in those cases in which the cause had acted suddenly the disease was more likely to be at once fully developed, whereas in the cases in which the nervous system became more gradually undermined there was progression of the symptoms to their severer degree of manifestation. Among the premonitory symptoms were found more particularly a feeling of malaise, of some impending illness, headache, drowsiness, perhaps stiffness of some of the muscles, with shooting pains in the limbs. These symptoms gradually became aggravated, and tetany then set in. Both hands assumed a peculiar position, though not always the same; varying according to the several groups of muscles affected. In most cases it was the muscles supplied by the ulnar nerve which suffered, in some those under the control of the median, while only very occasionally those which received their motor impulse through the musculo-spiral were affected: therefore a common position of the hand in tetany was a conical one, the thumb being forcibly adducted, the fingers pressed against the thumb, the wrist bent and turned towards the ulnar side of the arm. The condition might stop there or proceed higher up, the forearm be bent, the arms strongly adducted to the body. While a considerable variety of positions might be produced according to the muscles affected, there was in true cases of tetanus always some degree of rigidity in the muscles supplied by the ulnar nerve, and where this was entirely wanting the case was probably not one of tetany. The muscles of the lower limbs might also be affected, causing flexion of the toes, the heels to be drawn up, or the toes might be widely separated, the knees extended, etc. In some cases only one side of the body was affected, or only the upper limbs, or the lower, or the limbs might be affected alternately, but usually there was symmetrical affection of both sides of the body. In the large majority of cases only the muscles of the extremities were affected, but in some those of the head and body were involved. In extreme instances there was spasm of the glottis and dyspnœa, and the diaphragm and other mus-

cles of respiration appeared to be fixed. If the patient was not speedily relieved, death would take place from apnœa. Even the bladder might be affected. A very severe attack sometimes ended in profuse perspiration. The contraction of the muscles was sometimes very painful, more especially in children; in other cases there was only a stiff and bruised feeling, with tenderness on pressure. The degree of contracture might vary from one minute to another; in some cases the patient lay stiff in bed like a statue; in some the degree of muscular spasm was moderate, allowing of some movement. To overcome the rigidity caused pain. Sudden impressions by cold and heat would arrest the spasm for a moment. The duration of the attack was variable; it might last only five minutes, or as many hours; where it had been said to have lasted days together, there probably had been brief intervals of relaxation unnoticed by the attendant; otherwise he should say the case was not one of tetany.

Regarding Trousseau's symptom, causing the spasm by tightly bandaging the leg, Dr. Althaus thought it might be produced by either pressure on the blood-vessels or nerves, but compression of the femoral artery brought about muscular rigidity much more quickly than did compression of the nerve in the sciatic notch. Trousseau's symptom was one diagnostic mark between tetany and hysterical contracture: in the latter the use of the Esmarch bandage being followed by relief from the contracture. The electrical and mechanical excitability of the nerves and muscles was enhanced. If the electrical currents had become again normal, it might be concluded that the patient had recovered. The mechanical irritability was especially marked along the portio dura, even when it had not been previously affected during the disease; during the free intervals there was decided loss of muscular power, together with a feeling of lassitude.

While tetany showed a great variety of symptoms in the motor sphere, these were much less conspicuous in that of sensibility. Some patients claimed that pain was insignificant, but it was usually to be elicited over the spine, particularly the seventh cervical vertebra. Feelings of cold and heat, etc., were sometimes present, sometimes absent; sometimes there was redness and œdematous swelling, more especially of the joints of the fingers and toes, leading us to suspect rheumatic fever. The temperature might rise as high as 101° F., or higher, in severe cases. Usually the secretions did not manifest any morbid change.

A few cases of tetany had ended fatally, but precise pathological data had not been obtained. The great diversity and variety of changes found was in itself proof that we had not yet discovered the lesion of tetany; while other considerations led him to think that, if there was a particular lesion, it was one causing only a functional disturbance in the giant-cells of the anterior horns of gray matter in the cord. Hughlings-Jackson's theory regarding the cerebellum as being the seat of the trouble he thought was far-fetched.

The diagnosis of tetany was not always easy. We had to rely chiefly on the paroxysmal occurrence of the spasms, the peculiar fact that it spread from the periphery to the centre, on Trousseau's symptom, and on the electrical and mechanical excitability of the nerves and muscles. It was to be distinguished from epilepsy, cerebro-spinal meningitis, rheumatism, tetanus.

Passing to the symptoms of tetanilla, the author said it occurred in neurotic patients, frequently in those addicted to masturbation. In some cases there was no apparent cause for it. Unlike tetany, in it the spasms were clonic; there was absence of prolonged muscular resistance and Trousseau's symptom. The convulsions were symmetrical, and ceased during sleep. There was generally impaired motor power or power of co-ordination. The nutrition of the muscles was normal, but the excitability was increased, and the knee-jerk more especially was exaggerated. The degree of spasm varied. In some cases it was slight, in others of considerable severity; in some temporary, in others almost incessant. The flexors of the hands were frequently involved, sometimes the deltoid; and, indeed, none of the muscles of the body were exempt. Perfect rest gave the greatest ease; while walking, using the hands, etc., were liable to increase the spasms. The patient might be unable to follow his occupation, but it was chiefly the moral influence from which the patient most suffered, fearing a cerebral tumor, progressive muscular atrophy, etc. All of his patients had recovered but one. In this one the disease commenced when he was sixteen, and there were now and then recurrences, although his general health was good, at the age of fifty-four years. He was disposed to think that tetanilla was due to the same condition as tetany, only in a less marked degree: namely, a disturbance of nutrition in the giant-cells of the anterior horns of gray matter.

As to the prognosis in tetany, most persons recovered within two or three months, especially if under favorable circumstances. He recommended, as treatment, healthful surroundings, nourishing food, special treatment for special conditions; chloral hydrate was better than morphine as a direct sedative; iodide and bromide of potassium had been useful in some cases. Electricity had frequently been employed without success when applied to the affected nerves and muscles, while the application of the large anode to the spine, with the cathode at a distance, seemed to have a much better sedative effect. For cutting off an attack of tetany threaten-

ing life, nothing was equal to the subcutaneous injection of pilocarpine. As soon as profuse perspiration was established the spasm ceased. The treatment of tetanilla should be chiefly mental, especially assuring the patient there was nothing wrong with his brain.

Dr. W. A. Hammond said it would be impossible for him to add anything to the very graphic description Dr. Althaus had given of tetany. He thought he had seen a good many cases of tetany; but he had only recognized four, the other cases having come under observation before he knew anything about the disease. It was his opinion that many of the cases recognized as tetanus during the time of the civil war were cases of tetany, for usually they recovered. He had seen probably forty or fifty such cases, and all had recovered. It was well known that the idiopathic variety of tetanus was more likely to be attended by recovery than the traumatic variety.

Dr. Hammond gave some of the differential points between tetany and tetanus: among others, the commencement and principal seat of the affection being in the lower jaw in tetanus; in tetanus there was epigastric distress; the more marked reflex excitability in tetanus; and in tetany he had almost always found some disturbance of sensibility, paræsthesia and anæsthesia.

As to the probable seat of the disease, he could not conceive how it could be due, as supposed by Dr. Althaus, to a change in the giant-cells of the anterior horns. Dr. Hammond was rather disposed to think it existed in the cells of the antero-lateral columns, but not confined there; extending also to some extent to the posterior columns.

Of the cases which he had seen, two recovered probably without benefit from the drugs administered; two recovered promptly within four or five days after the administration of large doses (one-hundred-grain doses) of bromide of potassium.

Dr. E. Darwin Hudson did not think that clinicians generally could accept tetany as a distinct disease. The symptoms which it included, as given by different authors, were too varied.

Remarks were also made by Dr. Heitzmann, Dr. Corning, and Dr. John C. Peters, and the discussion was closed by the author, who said that in England they would not dare administer one-hundred-grain doses of bromide of potassium.

CONTRA-INDICATION TO THE USE OF PARALDEHYDE.—Sommer (*Neur. Centr.*, No. 11) concludes that paraldehyde ought not to be given to patients presenting atheromatous defects, and should not be employed in connection with alcoholic liquids. Eickholdt holds that the presence of vaso-paralytic symptoms precludes the employment of paraldehyde.

REVIEWS AND BOOK NOTICES.

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE, DESIGNED FOR THE USE OF PRACTITIONERS AND STUDENTS OF MEDICINE. By AUSTIN FLINT, M.D., LL.D. Sixth Edition, Revised and largely Rewritten by the Author, Assisted by WILLIAM H. WELCH, M.D., etc., and AUSTIN FLINT, M.D., LL.D. Philadelphia, Lea Brothers & Co., 1886. 8vo, pp. 1160.

By careful condensation and rearrangement, and by the omission of obsolete matter, much new and valuable material has been added to the present edition without increasing its bulk. Among the new articles special attention is attracted to the following: Infectious Tumors, Syphilitic Disease of the Lungs, Cerebral Syphilis, General Considerations relating to Inflammatory and Structural Disease of the Spinal Cord, Spastic Cerebral Paralysis of Children, Hereditary Ataxia, Myxœdema, Multiple Neuritis, General Pathology of Pyrexia, and Milk-Sickness. In addition to these, the entire work had been revised by the author previous to his death, and many articles rewritten. As with the preceding edition, the present has had the advantage of revision in conjunction with Dr. Welch, of Johns Hopkins University, who contributes also the first seven chapters and part of the eighth. It was issued under the immediate supervision of Dr. Welch and the author's son, Professor Flint, of Bellevue College, New York. Some diagrams have been introduced to elucidate the subject of the physical diagnosis of cerebral diseases.

By the use of small, though clear, type and the sparing use of illustrations, it has been found possible to present in one volume a work on the practice of medicine which is encyclopædic in its fulness. As a text-book or work of reference upon medical practice, it is the favorite with students and has received abundant evidence of appreciation by the profession.

INSOMNIA, AND OTHER DISORDERS OF SLEEP. By HENRY M. LYMAN, A.M., M.D. Chicago, W. T. Keener, 1885. Small 8vo, pp. 239.

This very interesting essay of seven chapters is more comprehensive than its title would indicate. The physiology of sleep, the ordinary agencies which disturb repose, and the devices for removing or overcoming them by moral and medical means occupy the first three chapters, the remaining four being devoted to the treatment of insomnia in particular diseases, a consideration of dreams, somnambulism, and artificial somnambulism or hypnotism. Recent investigations in telepathy are elucidated by clinical cases, and metaphysical healing is explained by the author upon logical grounds.

MISCELLANY.

PROFESSOR E. WILLIAMS, OF CINCINNATI.—It is announced that, owing to the precarious state of his health, Dr. Williams has been obliged to relinquish professional engagements and to visit California. He has also resigned his presidency of the Section on Ophthalmology in the International Medical Congress, a step that causes universal regret.

DR. D. HAYES AGNEW has purchased the residence of Dr. R. J. Levis, on the northwest corner of Sixteenth and Walnut Streets, Philadelphia, and will shortly remove his office to this place. Dr. Levis has gone to Europe for a prolonged stay.

NOTES AND QUERIES.

IN MEMORY OF DR. F. H. HAMILTON.

The Society of Medical Jurisprudence and State Medicine held a meeting in memory of Dr. Frank H. Hamilton, its late President, at the Hall of the Academy of Medicine, New York, September 30, 1886. The opening address was made by the Hon. Amos G. Hull, Vice-President of the Society; after which Dr. Charles A. Leale, President of the New York County Medical Association, delivered an extended eulogy of Dr. Hamilton, in the course of which he gave an exhaustive review of his career and his eminent services to surgery and to the profession and society at large. The Secretary, Dr. G. W. Wells, then read a tribute to the deceased, prepared by General Calvin E. Pratt, which was followed by brief addresses by Drs. Austin Flint, John Shrady, C. S. Wood, Nathan Bozeman, Messrs. Kitchell and Russell, and by other members of the medical and legal professions.

The following resolutions, offered by Dr. Leale, who was the chairman of the Committee of Arrangements for the memorial meeting, were unanimously adopted:

"*Whereas*, The medical and legal professions have sustained a sad bereavement in the death of Professor Frank Hastings Hamilton, A.M., M.D., LL.D., late President of the Society of Medical Jurisprudence and State Medicine, which occurred at his residence on the eleventh day of August, 1886; and

"*Whereas*, It is eminently proper for us, in our associated as well as private relations, to express our great admiration of the life and character of one who has done so much to elevate Medico-Legal Science; therefore

"*Resolved*, That as a Society composed of members representing two of the learned professions which he labored so hard to advance and harmonize, we add our tribute of loving esteem.

"*Resolved*, That Dr. Hamilton, from his pre-eminent talents and his position as a teacher, writer, and practitioner, covering a period of over half a century, has been the means of deciding many perplexing questions coming properly within the jurisdiction of our Society, and has thereby greatly relieved the professions from the malice of unwarrantable litigations.

"*Resolved*, That the humanity, benevolence, and fixedness of purpose exhibited during many years of constant professional toil under numerous trying circumstances, ever with the sincere desire to promote his art and benefit mankind, have ennobled his character and left to us a name worthy of our highest emulation.

"*Resolved*, That the example of his life, diligent study in early youth, manifest desire to acquire knowledge by carefully searching the museums of America and Europe for anatomical specimens to settle disputes in surgical pathology, his translations of foreign medical works, his careful and accurate teachings united with a stern integrity ever to be truthful, and last, but not least, his monumental volumes on Fractures and Dislocations which have been the standard works recommended by colleges at home and abroad, and remain to-day unequalled in surgical literature, having been translated into many foreign languages, and are the acknowledged authorities wherever surgery or medical jurisprudence are taught,—these with many other honorable characteristics have justly endeared his memory to every true and faithful member of our professions, and placed his name upon the scroll of the illustrious men of the first century of American history."

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 10, 1886, *TO OCTOBER* 23, 1886.

MAJOR WARREN WEBSTER, SURGEON.—Leave of absence on account of sickness further extended one year, on account of sickness. S. O. 244, A. G. O., October 20, 1886.

CAPTAIN DANIEL WEISEL, ASSISTANT-SURGEON.—Relieved from duty at Fort Steele, Wyoming, and ordered to proceed to and take station at Fort McKinney, Wyoming, reporting to the commanding officer of that post for duty. S. O. 135, Department of the Platte, October 15, 1886.

CAPTAIN B. D. TAYLOR, ASSISTANT-SURGEON.—From Department of the East to Columbus Barracks, Ohio.

CAPTAIN L. S. TESSON, ASSISTANT-SURGEON.—From Department of Texas to Department of the East.

FIRST-LIEUTENANT C. C. BARROWS, ASSISTANT-SURGEON.—From Department of Arizona to Department of the East.

FIRST-LIEUTENANT F. R. EGAN, ASSISTANT-SURGEON.—From Department of Arizona to Department of Texas.

FIRST-LIEUTENANT F. V. WALKER, ASSISTANT-SURGEON.—From Department of the East to Department of Texas. S. O. 244, A. G. O., October 20, 1886.

FIRST-LIEUTENANT E. C. CARTER, ASSISTANT-SURGEON.—Granted leave of absence for six months, with permission to apply for an extension and to go beyond sea, to take effect when his services can be spared. S. O. 244, A. G. O., October 20, 1886.

FIRST-LIEUTENANT EDWARD EVARTS, ASSISTANT-SURGEON.—Ordered to proceed to Fort Grant, Arizona Territory, and there take station. S. O. 94, Department of Arizona, October 1, 1886.

FIRST-LIEUTENANT W. W. R. FISHER, ASSISTANT-SURGEON.—Ordered, on expiration of his leave of absence, to report to the commanding officer at Fort Bidwell, California, for duty as post-surgeon. S. O. 93, Department of California, October 4, 1886.

FIRST-LIEUTENANT GUY L. EDIE, ASSISTANT-SURGEON.—Having returned from detached service in the Department of Arizona, will join his station at Fort McIntosh, Texas. S. O. 144, Department of Texas, October 13, 1886.

FIRST-LIEUTENANT CHARLES S. BLACK, ASSISTANT-SURGEON.—Granted leave of absence for two months on surgeon's certificate of disability, to take effect when his services can be spared. S. O. 244, A. G. O., October 20, 1886.

FIRST-LIEUTENANT ALONZO R. CHAPIN, ASSISTANT-SURGEON.—Relieved from duty at Fort Laramie, Wyoming, and ordered to Fort Washakir, Wyoming. S. O. 137, Department of the Platte, October 19, 1886.

FIRST-LIEUTENANT FRANCIS J. IVES, ASSISTANT-SURGEON.—In obedience to instructions received from the Division Commander, ordered to report in person at Headquarters, Department of the Platte, for duty. S. O. 146, Department of Texas, October 16, 1886.

FIRST-LIEUTENANT WILLIAM P. KENDALL, ASSISTANT-SURGEON.—Leave of absence extended fifteen days. S. O. 239, A. G. O., October 14, 1886.

FIRST-LIEUTENANT W. B. BANISTER, ASSISTANT-SURGEON.—Assigned to duty at Fort Wingate, New Mexico. S. O. 97, Department of Arizona, September 29, 1886.

FIRST-LIEUTENANT CHARLES F. MASON, ASSISTANT-SURGEON.—Relieved from temporary duty at Fort Verde, Arizona Territory, and ordered for duty at Fort Huachuca, Arizona Territory. S. O. 99, Department of Arizona, October 12, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED OCTOBER 23, 1886.

URQUHART, F. M., PASSED ASSISTANT-SURGEON.—Relieved from duty at Cape Charles Quarantine, to proceed to Washington, D.C., with steamer "Woodworth," October 20, 1886.

WASDIN, EUGENE, PASSED ASSISTANT-SURGEON.—Promoted and appointed Passed Assistant-Surgeon from October 1, 1886, October 20, 1886.

WILLIAMS, L. L., ASSISTANT-SURGEON.—Granted leave of absence for three days, October 16, 1886.

PHILADELPHIA, NOVEMBER 13, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE ON CEREBRAL SYPHILIS.

Delivered at the Hospital of the University of Pennsylvania

BY WILLIAM PEPPER, M.D., LL.D.,

Provost of, and Professor of the Theory and Practice of Medicine and of Clinical Medicine in, the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—I saw this man for the first time about three weeks ago. While in a neighboring city I was asked to see him in consultation. I examined him with care, and it was decided that he should come here to be treated. I can only give you the history as it was told to me at that time, for the condition of the patient is unfortunately such that he can give us no reliable information. He has been a hard-working man. He contracted syphilis many years ago. He had few secondary symptoms, and was regarded as absolutely well. He then married, and has had three perfectly healthy children. He has been somewhat overworked, but not sufficiently so to justify his present broken-down condition. About two years ago he fell down a hatchway, producing a bad fracture of both bones of the right leg, and striking himself on the back; and he also received injuries about the head. There was no fracture of the skull, nor were there any symptoms of concussion of the brain. I call particular attention to this, because it has an important bearing on the symptoms which he presents. Previous to this accident he had begun to complain of headache of the most persistent character. This became increasingly severe after the fall. It was several months before he was able to be about. It was then noticed that there was some peculiarity in walking; but this may have been due to the fracture of the leg. It was supposed that the symptoms were merely the result of the shock to the system from the violent fall. About last January (eight months ago), he had a severe general convulsion, with entire unconsciousness, and with muscular movements involving both sides of the body. Since then the convulsions have recurred at irregular intervals. With this there has been a progressive failure of the intellectual powers. His mind has been growing dull, and his memory weak and confused. The eyesight has failed somewhat, and his gait has become more unsteady; the headache has continued, but is not so severe as formerly.

Present Condition.—He is without fever, or at the most has had an occasional trifling rise of temperature in the evening to 99.6°, and on rare occasions to 100°. He often passes days without any elevation of temperature. I would note that since his admission, eighteen days ago, there has been on three occasions a temperature of 100°, and several times it has been 99°, showing an irritative condition of the system. He has a rather surprised, bewildered expression on the face. His memory is confused: he was in the hospital several days before he could realize where he was. He was much worried about his children, asking continually how soon he would be able to go back to them. In other respects there seems to be no mental aberration. He can read fairly well. The pupils react both to light and accommodation. There is no paralysis of the facial muscles or of the tongue. Hearing is not affected. The knee-jerks are increased, perhaps on the right a little more than on the left. The other reflexes are not increased. There is some slight enlargement of the glands in both groins. I do not know that this is to be regarded as syphilitic, but I mention it on account of the history which we have obtained. There are sometimes slight twitches in the muscles of the eyes, and occasionally a little approach to nystagmus, but this is not marked. When the hands are stretched out there is marked muscular tremor. There is some slight ataxia in the conjoined movements of the arms and hands. In the legs there is no loss of power, and the affection of the gait does not seem to be greater than might be explained by the rather badly healed fracture of the right leg. There is some tremor in the lower extremities. He stands well with the eyes shut. He complains slightly of pain in the back, and of a feeling of coldness, which he has had since admission.

The eyes were examined by Dr. George E. De Schweinitz, who makes the follow-

ing report. "The action of the pupils is good, the right pupil being slightly larger than the left. The excursion of the eyes is good, except laterally to the right, when the movement is arrested with a jerk. There is no paralysis of any of the muscles, but insufficiency of the internal recti, between six and seven degrees. The eye-ground of the left eye shows the disk oval, the veins normal in calibre. The disk is grayish red in color. The arteries are distinctly small, and in some places quite contracted. The lymph-sheaths along the arteries are full, but not so along the veins. The right eye shows a large, irregular-shaped nerve, with central excavation, and a similar condition of the arteries and veins as noted in the left eye. Central color-perception is good in both eyes. The field of vision is contracted more on the left side than on the right. The diagnosis is gray degeneration of both optic nerves."

The following notes have been made since admission.

September 28, the day following admission. He complains of loss of memory; does not recognize individuals, and recurs to the same subject constantly; but there are no distinct hallucinations.

September 30. Had severe convulsion at 3 P.M. It began with a cry, and was followed by twitching of the left side of the face; then by convulsive movements of the right hand and arm; then of the right side of the face. There was some increased flow of saliva, with frothing. Some loss of power of deglutition and nystagmus accompanied it. The convulsion was diminished by inhalation of nitrite of amyl. The patient was then laid upon the bed. He was then seized with a general convulsion of severe character, lasting ten minutes, accompanied by profound loss of consciousness, by frothing at the mouth, by livid discoloration of the face, and by universal clonic movements. Twenty grains of chloral hydrate were given by the rectum, and half an hour later twenty-five grains of potassium bromide were administered by the mouth.

Here, then, is a case of great gravity, one not unattended with obscurity, where it is exceedingly important that we should arrive at an accurate diagnosis to guide us in its treatment. In the first place, as to the diagnosis of this case. You will observe that we have two distinct morbid influences to study. First, the effect of the injury, the concussion of the spine, with the asserted injury of the head, although there were no evidences of severe injury of the skull or brain; and, secondly, the effects of the old syphilis, with some evidences of constitutional infection, but with a long period of quiescence, during which healthy children have been born to him. It seems impossible to consider that this condition is due to the injury. There is undoubtedly a lesion within the cranium. This probably might be produced by an extensive creeping meningitis which had involved the sheaths of the optic nerves and led to degeneration of the nerve-trunks. This might have been set up by an injury: a fissured fracture or a depressed fracture, with a spicule of bone irritating the surface of the brain, might excite a subacute process extending along the base and giving rise to these symptoms. From the history of the injury which we have been able to obtain, I think that it is not reasonable to believe that the accident really was followed by such serious lesions within the cranium. This condition might be dependent upon an inflammatory lesion arising under the influence of the old syphilis. A syphilitic meningitis or a syphilitic gumma developing in the membranes and involving the surface of the brain might cause the symptoms which this man has presented. From a survey of the whole case, we cannot help feeling that the evidence points strongly to the syphilitic origin of the trouble. The gravity of the nervous symptoms has been no doubt influenced by the severe nervous shock accompanying the injury; but that the whole trouble is traumatic I think cannot be maintained.

Cerebral syphilis is one of the most common expressions of constitutional syphilis. The anatomical lesions are gumma —that is, an isolated tumor growing in the membranes and encroaching upon the surface of the brain by pressure—and meningitis involving the arachnoid or the dura mater or periosteum. Of course, the inflammation of the dura is practically an internal periostitis. These are the common lesions. Among the symptoms which we note in cerebral syphilis, headache is the most constant, often being violent and continuous, lasting for days or weeks. Convulsion is an extremely frequent symptom, the character of the con-

vulsion differing according to the lesion. When the lesion is very circumscribed, for instance, a small gumma involving some cortical centre, we may have distinctly-marked, circumscribed spasm of some part of the body, which may be limited to a single member, as the arm or the muscles of the hand, or those of the face; or the convulsions may be general. Sometimes the spasm can be traced to certain groups of muscles where it will begin, and whence it will spread until the whole area which is to be involved is affected. A careful study of this point is of great importance when we come to consider the possibility of determining the exact location of the lesion in this and similar cases. In those convulsions dependent upon a circumscribed lesion, consciousness may not be entirely lost, or it may not be lost at all. On the other hand, the irritation may be so great that from this centre which starts the convulsion in one group of muscles the irritation will spread to other centres, producing loss of consciousness, and later even general convulsion. Another important symptom is the lesion of the optic nerve: that is, gray degeneration and atrophy. This case illustrates the importance of the ophthalmoscopic examination in all such cases. This man reads fairly well, and he complains of no dimness of vision. There may be advanced lesion of the optic nerve without any appreciable defect of vision as determined by the ordinary standards. Next in importance are lesions of other intracranial nerve-trunks attended with local palsies, as of the face or of the muscles about the eye. The only symptom here is insufficiency of the internal recti; but it is not great enough to be regarded as significant. Then we have failure of memory and of mental power. This is dependent upon prolonged irritation, and sometimes upon actual softening from pressure by exudation, either from a gumma or from meningeal thickening.

The first question, then, of practical importance in the diagnosis of this case, after having determined the presence of cerebral syphilis, is whether the lesion is a diffused or a strictly circumscribed one. Now, this would not have been so important a few years ago as it is to-day. It is a fact that the study of cerebral topography and the localization of lesions connected with certain special symptoms has already advanced so far that we are able to define the precise position of a number of lesions within the cranium where certain specific symptoms are present; so much so that within the past year or two there have been several cases where trephining has been performed, the lesion found, and the growth removed, with recovery of the patient. The gumma, and in some cases the neoplasm of other character, has been as accurately located and removed as though it had been a superficial growth. The importance of determining whether the lesion is diffused or is circumscribed is at once apparent. All the evidence in this case is in favor of a diffused lesion. The double atrophy of the optic nerves, the mental failure, the loss of memory, and the character of the convulsion would indicate extensive lesion. As we have noted, the spasm begins on the left side of the face, then affects the right hand and arm and the right side of the face, and is followed by a general convulsion. This is not an indication that a minute cortical centre is affected, but points to a widespread disturbance of the motor centres. A diffused lesion, either a meningeal exudation or several gummata, would seem to be the diagnosis, and in all probability, from the diffused character of the headache, it is a meningeal lesion.

The treatment may be internal, and must be addressed to the syphilitic element of the case. He has been put on ascending doses of potassium iodide, with ascending doses of mercuric bichloride, so as to reach as rapidly as possible the point of tolerance of the system. The patient has been quieter during the past few days; but whether this is due to the treatment or to the fact that he is becoming more familiar with his surroundings cannot be determined. I shall bring him before you again in a few weeks, when we shall be better able to judge of the effect of treatment.

A New Professorship in the University of Pennsylvania.—We take great pleasure in noting the happy choice of the trustees of the University of Pennsylvania in their selection of Dr. Daniel G. Brinton, of this city, as Professor of American Archæology and Linguistics. Dr. Brinton has already attained distinction by his studies in the early dialects of the American Indians, and is a vigorous writer and lecturer.

ORIGINAL COMMUNICATIONS.

A CASE OF APHASIA, WITH REMARKS.

Read before the New York State Medical Society, Third District Branch, meeting at Binghamton, Sept. 17, 1886,

BY S. M. HAND, M.D.,
Norwich, New York.

(Continued from page 90.)

ALL teachers on the subject describe amnesic aphasia as a forgetfulness of words, and ataxic aphasia as a loss of the power of co-ordinating the movements necessary for the articulation of these words. Technically it is not a forgetfulness of words, but a loss of the faculty of creating internal words or word-images as representatives of ideas, for there is first an internal speech before it can be made external by articulation.

In the case I have related, intelligence is perfectly preserved, and questions and the value of words are as thoroughly comprehended as in her former normal condition, and when the word-image is presented by pronouncing it in her hearing her power of co-ordinating the movements necessary for the articulation of the word is excited to activity and acts as perfectly as it did in her normal condition. There are cases in which the co-ordinating power is lost while the internal word-creating power is normal; and there are cases in which this co-ordinating power is normal while the word-creating faculty is lost.

Vocal language is not altogether voluntary, but partly voluntary and partly automatic, by the same reason that walking and playing a piano are automatic in part, and even much of all we do is automatic, while much less is voluntary. In a case, therefore, of amnesic aphasia the subject may say, "How do you do?" or "I don't know," and not be able to repeat it if requested to do so. The case of the late Dr. Wicks, of Gilbertsville, illustrates an automatic power for speech. He was suddenly arrested, while walking on his lawn one morning, with a partial hemiplegia of the right side, and had lost the ability to speak. He could not say yes or no, or speak any other word except the sound "terita." When I asked him to say "cup," he looked at the cup (which stood on the table near him) and said, "Terita, terita," and repeated it; and then, with an expression of impatience by the gestures of his face, said, "Damn it." Then I asked him to say, "Damn it," and he said, "Terita, terita;" and, with the same expression of impatience, after the second effort he said, "Damn it." He could not speak a syllable voluntarily, but he did speak automatically, and showed that he was not ataxic, but that he was amnesic.

Another case which I recently saw illustrates a condition which is curiously unlike any of the fifteen cases described by Hammond. A man who is now 35 years of age, who had been a locomotive engineer five years ago, suddenly suffered partial hemiplegia of the right side and lost his ability to speak. The hemiplegia is so far recovered that he is now able to walk and to work some in the garden, but he has not been able to speak one word voluntarily since. The only sound he makes is "dĭna dĭna." He cannot write a word or syllable to convey an idea, but he can readily copy a written line. He can read a newspaper or a written sentence, and can count and make the figures to number his brothers and sisters and to express his age. When requested to write the name of his town he could not do it, but could find the name and point it out on the newspaper, or could copy it in printed characters from the newspaper. This is a case of partly amnesic and partly ataxic aphasia, for he can read, but cannot write nor speak, and can count and write the figures that express the numbers. He appeared willing to attempt anything that he was requested, and made an effort to write the name of his town, but could not do so; but he could write his name.

I was called, a few weeks since, in consultation with my neighbor in medicine, to see a colored woman, whom we found with partial hemiplegia of the right side and a much impaired ability to speak. She commenced every attempt to speak with "I want," and some of the time with only this expression; but with some attempts would add a word or two slowly. When she was requested to write her name she did so two or three times, but in all cases with a duplication of one of the letters of her name. Her name was Street, and she duplicated the first "t". When she was requested to write the word "blanket" she made a faithful attempt, but could not succeed with the first letter, nor of any other word she was requested to write. She was ordinarily able to write very well. It would seem as if her suc-

cess in writing her name was partially at least automatic. This could not properly be called a case of ataxic aphasia, but was a case of incomplete amnesic aphasia, for her articulation was perfect for the pronunciation of words, but with very difficult recollection of words, or with much impairment of the internal word-making faculty.

All language of course originates in the gray matter of the cerebral lobes, and it has been claimed by some that we think in a language. This has been questioned by others, and it might indeed be difficult to demonstrate the correctness of either position. But when we hear the word "orange" Ferrier says we think "orange," and the senses of smell and taste and form are concerned in our conception of the orange; and synchronously with this conception of the object the activity of the speech-centre is excited, and an expression by language results.

The portion of brain called hemisphere is not a single organ, as was supposed in former days, but consists of a number of thoroughly differentiated organs, each one of these having special endowments or functions and yet in closest possible connection with all the other portions of the hemispheres and lower brain-centres.

It is comparatively easy to describe the configuration of the various organs of the lower brain-centres and to determine the function of each, but not as easily possible to define the numerous parts and functions of the hemispheres. Indeed, the phrenologist assumes the necessary understanding by an examination of the external surface of the skull. But to define all these various parts of the hemispheres with accuracy, and to determine their intimate structure and their individual energies and offices, and the changes they are liable to undergo during their development and in results of diseases of them, is a work which at the present time is engaging the attention of the profoundest students and the shrewdest detectives of pathological observations.

However, the functions of some of the convolutions are even now pretty well known, and the exact relations of the various portions of the hemispheres anatomically are well known, but to localize the precise seat of power which the intellect uses to administer its government is not yet unquestionably settled. Of late years, Hitzig, Fritsch, and Ferrier have made experiments with the interrupted or faradic currents, and have assumed to be able to map out the convolutions of the front and middle parts of the hemispheres of animals into a number of precisely-limited areas, producing a limited but distinct movement by such stimulation of each; and, while stimulation of a large surface produced general convulsions, the movements were so precise that they answered each to the spot stimulated almost as completely as the note answers to a key struck on a piano. Although this would seem almost a demonstration of the localization of special power in these parts of the convolutions, Foster questions the conclusions, and says that "the exact nature of the connection between galvanic stimulation of the brain-surface and bodily movements is at present very obscure," but that "it is certain that these cerebral spots are not motor centres in a sense that the co-ordination of the movements takes place in them, because the most complete co-ordination obtains in the total absence of the cerebral hemispheres." He credits the probability that "the real connection between the gray matter of the convolutions and these movements with the co-ordinating mechanisms is placed lower down in the brain."

It has been observed when portions of the cerebral hemispheres were gradually removed that no effects were apparent on the intelligence or volition of the animal when the removal commenced, but as it continued greater dulness was manifested, and still greater, until finally intelligence and volition were entirely lost. All surgeons occasionally witness the results of violence when a portion of the brains of a man has been carried away without any marked effect on the physical condition of the patient. The exposed brain seemed not to be at all sensitive, and ordinary stimulants applied to the surface of the convolutions in nearly or quite all experiments have failed to produce any apparent effect. Hence the unbelief in the existence of any localization of functions in the convolutions of the hemispheres, and the belief of some that the brain acts as a whole and not in local parts.

But, we may ask, is the location of the faculty of speech in the human brain a possibility, and are all the lesions which inhibit the power of speech or derange its proper

expressions uniformly found at the same point? It has been so far investigated by experimenters and post-mortem observations of pathological lesions that it is conceded that the faculty of speech begins in the cerebral hemispheres and in the left frontal lobe, and still closer, in its third frontal convolution, and yet closer, in the posterior part of the left third frontal convolution, or—as it is believed by more recent observers from later deductions and comparisons—in the operculum of the island of Reil. Lesions occurring in other regions do not affect the speech unless indirectly through the circulation or continuous sympathy. Aphasias are never called into existence by lesions of the occipital lobes, except possibly in very rare instances by the incidental general disturbance of the hemispheres as a whole, or by a continuous extension that, with the local lesion of the posterior lobes, the convolutions of the anterior lobes, or the island of Reil, is involved with the foreign lesion.

The conclusions of no observer may yet be taken as absolute authority, while they may be entertained as very reasonable, for many are giving attention to the localization of the faculties of the brain, and so far conclude that this faculty of human speech is limited as a power to the region of the posterior part of the left third frontal convolution of the cerebral hemisphere, or in the island of Reil. These parts, it will be remembered, are not in direct continuous relations, but are in immediate contiguous relations. It is understood by all, while these points are themselves in a healthy state and the will orders the pronunciation of a word, that a defect of some subordinate brain-centre may prevent obedience to the order, because then there cannot be the necessary muscular co-ordination to execute the impulse of the will; and yet in such a case as here related, when the entire line of brain-power is surely perfect (as demonstrated by her easy repetition of the sound of the word and the perfect consciousness of her success), it is evident that there is a local lesion; and if in such cases there is uniformly direct or indirect disability of that particular point (as observed in many post-mortem examinations published by Hammond and others), then the conclusion is more than simply reasonable that there is a local centre of power through which the will originates the efferent impulse of speech.

Kussmaul, however, says, "For the purposes of speech there exists an apparatus as vast as it is complicated, consisting of nervous tracts and ganglionic centres, which partly occupy the position of the loftiest workshops of the conscious intelligence and of the will, and are partly reflex agencies, in which simple and ordered sensory stimuli are converted into motion. Such a thing as a simple *centre of language* or *seat of speech* does not exist in the brain any more than a seat of the soul in a simple centre.

"The central organ of speech is, on the contrary, rather composed of a large number of ganglionic apparatuses widely separated from one another, but connected by numerous tracts and fulfilling certain intellectual sensory and motor functions. But it is probable that none of these apparatuses subserve alone the objects of speech. The nervous mechanisms can be made serviceable for different purposes, and it is only practice which brings about those connections between ganglion cell and ganglion cell, between ganglionic centre and ganglionic centre, which render speech in its more restricted sense possible, as well as all the other so very numerous means of expressing our thoughts and feelings. In this sense alone is a central organ of speech gradually cultivated or, as some will say, created in the brain by language itself, and in this sense do there also exist central organs for the plastic art, for dancing, for music, for printing, and for the forms of thought which do not give employment to words, but to numerical signs and other pictorial formula."

But there is evidence which may not be gainsaid that disease of the superficial gray matter of the hemispheres causes delirium (as is so uniformly the case in meningitis), and sometimes convulsions either of an epileptic character or localized in particular groups of muscles; and this local power is also manifested by experiments with the galvanic current, because if the galvanism be applied to particular convolutions and to particular parts of convolutions, definite and uniform co-ordinate movements of various groups of muscles will arise. Thus experiments indicate, if they do not demonstrate, that even the intellectual power is not seated in the gray matter of the hemispheres as a whole, but that a special intellectual power has its residence in a particular portion of one or another of its

convolutions, or lobes, or islands, through which the will sends only the special or particular efferent force with which it is endowed, and receives the returning or afferent impulse to its central home of consciousness. Still, in what particular part or convolution all the various intellectual faculties reside is not yet known, for not all of them have been made the subject of special experiment. But the accidents of violence and disease, interfering with some of the important functions so convenient and necessary to the comforts and uses of men, as hearing and seeing and speaking, have induced an investigation of the condition of the lower and higher brain-centres, so that there is now striking pathological proof accumulated of the connection of certain movements concerned in the production of language with a particular convolution of the brain.

REVIEW OF THE PROGRESS OF MEDICAL AND SURGICAL ELECTRICITY.

BY WILLIAM R. D. BLACKWOOD, M.D.,

Neurologist to the Presbyterian Hospital.

THE TREATMENT OF INFANTILE PALSY BY GALVANISM.

"IN every case of infantile paralysis, so far from doing good, if persisted in, galvanism does infinite harm in the way of increasing the inevitable deformity. This occurs from the difficulty or practical impossibility of localizing the effects of galvanism on the palsied muscles. To be of any use, electricity must produce muscular contraction, effected in the case of galvanism by interruptions of the current. When a strong current is used,—and this is generally necessary,—the current diffuses and excites neighboring muscles. These neighboring muscles are frequently the physiological opponents of the affected ones, and the very ones of all others that it is undesirable to strengthen by unnecessary use or stimulation," etc.—Leslie Phillips, M.D., *British Medical Journal*, July 10, 1886.

It is just because electricity is carelessly used, as above said, that it either fails or does harm. That it can injure in cases instanced as above is preposterous. In the first place, stabile galvanism increases nutrition locally in muscles *without* interruption. Secondly, muscles *can* be isolated far enough to exclude any such calamitous injury as above described, and interrupted currents used to great advantage; and, thirdly, it is not necessary to use *strong* currents at all. Long-continued *mild* applications are preferable: they neither frighten nor fatigue the child, and they accomplish all that is required from electricity, as our hospital cases particularly indicate.

GALVANISM IN PRURITUS.

Breda gives (*Giorn. Ital. delle Mal. Ven. e della Pelle*) additional cases thus treated, in continuation of his former paper on the subject. Universal pruritus yields in four to six weeks' treatment, but how often applied he does not state. We find relief to follow much sooner under daily treatment, the cure being usually arrived at in a fortnight.

GALVANO-CAUTERY IN PROCIDENTIA UTERI.

Dr. John Byrne, of Brooklyn, has been treating procidentia with the cautery, and he finds the method preferable to others in most instances. His operation consists in drawing the uterus down and encircling the cervix with the wire loop just below the reflection of the membrane forming the vaginal vault. A groove about a quarter of an inch deep is then made, and glycerole of tannin tampons applied. In cases reported he claims that in two or three weeks after operating no reasonable force will depress the womb. The health in all instances was perfect thereafter, and menstruation normal and free from pain or inconvenience.

GALVANO-CAUTERY IN MEMBRANOUS DYSMENORRHŒA.

In a Paris letter to the *British Medical Journal* of September 25, a paper by M. Landouski, read at the Medical Congress held at Nancy, stated his experience with the cautery in this affection, which was favorable. The cautery, (after full cervical dilatation) was lightly brushed over the endometrium, and the patient kept in bed a week.

This procedure was brought before the County Medical Society of this city by myself ten years ago, but the operation was deemed unadvisable by those who discussed my paper on dysmenorrhœa. The cases narrated at that time have *remained cured*, but my experience since is limited to two cases only, one much relieved, and

the other partially so. In these instances dilatation alone was unavailing.

HÆMOSTATIC ACTION OF UTERINE FARADIZATION.

Ramas, of Brazil, in the *Bulletin Générale de Thérapeutique*, No. 1, 1886, gives notes of a case of constant hemorrhage following an abortion. No foreign body was detected in the uterus, and ergot, iron, injections, tampons, etc., were useless. Electricity then stopped the flow, one pole to the cervix, the other on the abdomen.

ELECTRICITY IN GYNÆCOLOGY.

At the recent meeting of the American Gynæcological Society, during the second day's session, Dr. Engelmann, of St. Louis, and Dr. W. H. Baker, of Boston, read papers on the general and special uses of electric treatment in this department. A report of the session is given in the *Times* for October 16.

From the discussion there and at other times, it is evident that much of the imperfect or bad results attributed to electrolysis depends upon confounding the value of galvanic with induction currents. The faradic machine cannot give the desired effect when electrolysis is desired, as its power here is almost *nil*. A study of Amory's valuable work, lately published in the current series of "Wood's Standard Library," would repay those who desire to employ electricity intelligently in all departments of practice.

NOVEL METHOD OF ELECTROLYSIS IN THORACIC ANEURISM.

Mr. Richard Barwell reports the details of a case in the *Lancet* of June last. The lesion was at the aortic arch, and failure of other treatment led to the employment of electricity, the case being in a critical state. The idea of diffusing the current widely *within* the sac led Mr. Barwell to introduce a long coil of steel wire. The wire was rolled on a wooden spool, and after introduction of course assumed a coiled shape. When the cavity was well filled, the current from eight elements was used, the positive to the wire, the negative on the dorsal aspect of the thorax. Resistance being too great, twenty additional cells were added, and the strength of current limited to ten milliampères. This was maintained for eighty minutes, causing no inconvenience other than slight redness of the back. For twelve hours consolidation was not apparent, but then it rapidly increased, the tumor becoming quite hard, and pulsation almost ceased. The cough was much relieved, the general health appeared better; but in a few days a new tumor developed to the right of the sternum. The man died exhausted, and at the autopsy the coils were found to be coated by a thick coat of colorless fibrin, which bound the wire at many points firmly to the sac-wall.

Mr. Barwell points out the fact that the operation was undertaken too late, as the auxiliary tumor had shown itself two years before, and it was this one that ruptured. He believes, from the result, that his plan as here tried is greatly superior to the introduction of needles, as the clot is firmer, it is more extensive, and it is retained in place by the coil. The method is certainly worth extended trial; but, after all, the main point is prompt interference, and the time usually occupied in the administration of iodine, etc., is time lost.

MAGNETIC OPERATION ON THE EYE.

Dr. Jany, of Breslau, notes the removal of a steel splinter from the eye of a mason. The lids were intact, and slight ecchymosis on the upper edge of the cornea was present. The foreign body lay on the retina near the equator, a little outward from the vertical meridian, and it was apparently suspended by a fine, veil-like, white membrane. An incision in the conjunctiva under cocaine permitted the entrance of a fine pointed rod attached to a Voltolini electro-magnet, which was held near the chip for a few seconds before removal. The first attempt grasped the object, which was two and a half millimetres by one and a half by one-fourth, and three-edged. In three weeks the man was well, without scar, and his sight as good as ever.

Dr. Jany suggests a powerful magnet as more likely to attract at some distance, to hold the body if firmly embedded, and to save repeated attempts at removal. In this instance eight elements were employed to energize the magnet. The procedure is within the ability of any practitioner, in his opinion,—which opinion, however, we do not share.—*Deutsche Med. Wochensch.*

ELECTRICITY IN NERVOUS CARDIAC PALPITATION.

Meyer, Remak, Huchard, Eulenberg, Ziemssen, and others advocate galvanism

applied in different ways for the relief of nervous palpitation, and Duchenne advocates faradization. The latter, however, has failed in most cases in the hands of others than Duchenne. The experiments of Ziemssen show the effect of the constant current on the heart to be like that on striped muscle, and the poles applied to the thorax are as efficacious as in any other manner.

As stated in our last review, we do not favor direct electrization of the heart as described in that paper: but the anode may be placed on the neck (auriculo-maxillary fossa), the cathode over the præcordia. Skorczewski, in a paper on this subject, noted diminution of the apex-beat of from ten to thirty pulsations in a few minutes under galvanism. — *Zeitschrift für Therapie.*

THE EFFECT OF THE ELECTRIC LIGHT UPON THE EYE.

Dr. J. A. Andrews, of New York, read a paper on this subject before the recent meeting of the American Ophthalmological Society, contrasting the usual agents for producing light,—gas, oil, and electricity. Concerning in-door illumination, he finds that the maximum of light with the minimum of heat is obtained by the incandescent system of electric lighting. All cases of injury to the eye have, he states, been due to incautious exposure at close quarters to the arc-light. Out of eleven hundred workers using incandescent lights, not one case of injured vision was detected. Drs. Agnew and Mittendorf, of New York, corroborated the views of Dr. Andrews.

In one of the mills operated by a member of the writer's family, five hundred incandescent electric lights were, two years ago, introduced in the spinning department, in which very fine work renders the eye-strain great, and the improved work accomplished under the system is highly conclusive of the superiority over gas. The absolute steadiness, the whiteness, and the low heat radiated conduce decidedly to the comfort of the operatives, and finer grades of black are now produced at an increased rate in the same time under electric lighting when compared with gas. There is no doubt whatever in my mind, from close study, that improvement has taken place in the cases of a number of hands suffering from errors of refraction. Headaches, once common from strain and heat, are now rare. The necessity for elevating gaslights above the machinery to avoid fire is done away with, and the loops are brought down below the former line, so as to hide the light from the eye, the porcelain disks throwing the most of the light downward, yet, from their translucent nature, permitting sufficient to pass upward for illuminating the room itself. The sense of security from fire, the knowledge that no injury can come from touching the fixtures, and the absence of heat have changed the hygienic condition so much as to make necessary the extension to five times the amount this winter, leaving the superiority of the light itself out of the question. Physicians in any way connected with extensive factories might improve the comfort and health of the employees radically by a little study of this subject.

Since writing the above, inquiry among compositors in two newspaper-offices here and in others in New York shows similar satisfaction as to the hygienic influence of incandescent electric lighting over gas. Much more work with less fatigue to the eyes is accomplished by printers now than before in the same establishments, and they particularly remark the lessened tendency to headache, which is not uncommon in such operatives.

THE RETARDATION OF RETINITIS PIGMENTOSA.

This, as a rule, incurable affection has, in the hands of Dr. Hasket Derby, of Boston, improved under galvanism, and similar testimony was given by Dr. Standish. Dr. William S. Little had decided improvement in one case under faradism, and Dr. L. Webster Fox found that the negative pole was the more efficacious.

ELECTRICAL DOSAGE.

At the recent meeting of the American Neurological Association much discussion was had, without coming to any conclusion, as to dosage, thickness of rheophore coverings, shape and size of rheophores, etc., all of which is hardly worth discussing. A reliable milliampère-metre, such as Fleming's or Barrett's, should always be included in the circuit when using galvanism, and the matter of thickness of coverings is simply one of resistance to be overcome by potential. A thin cover is just as good for most purposes as a thick one, and entails no waste, and, provided

that the current is not "very strong" (seventy-five to one hundred and fifty milliampères), the lighter the cover the better. Caustic effect being avoided, we need care little for the points discussed, and the ultra refinement of theoretical electricians simply befogs inexpert men, who see in such disquisitions imaginary difficulties in practical work.

ELECTROLYSIS IN NÆVUS.

Dr. John Duncan, surgeon to the Royal Infirmary of Edinburgh, believes that the mixed and subcutaneous varieties of nævus are those specially adapted to this method of treatment. The certainty of cure without scarring on exposed parts is of much importance. Care must be taken to avoid a cutaneous slough: hence not too much should be attempted at each sitting. He prefers steel needles insulated with vulcanite, about a quarter of an inch of the point being exposed. Both poles are introduced, and an anæsthetic is used, the burning being severe.—*Braithwaite*, July, 1886.

Dr. A. Mayor, of Geneva, Switzerland, reports a cutaneo-subcutaneous case of nævus in a girl of 10 months, in which two sittings were successful in destroying the erectile tumor. The mass was the size of a nut, and four years after removal the child remained well and free from scar.—*British Medical Journal.*

IMPROVED AND NEW APPARATUS.

Dr. Rudisch has devised an arrangement by which a mass of asbestos is clamped between the collective and distributing plates, which after immersion for a time holds sufficient moisture to energize the couples for a month. The cells can hence be left at home, at least in zinc-carbon elements (or any single-fluid cell), and portability is thus enhanced. The plan is somewhat similar to that noticed in our review of March 6, 1886, in which agar-agar is employed by M. Guérin. With asbestos-paper internal resistance would not be heightened, however, as it is by the former plan.

IMPROVED GRAVITY CELLS.

Those who employ the ordinary Callaud cells are aware that carelessness in handling them is destructive to the separation of the liquid contents. Any injudicious blow on conjunctive wires is certain to stir up the cupric sulphate, and, as the zinc should never be touched by this solution, the waste thus caused is expensive. The Partz Electric Company has produced a cell (shown in the illustration) which cannot be disturbed thus, and which not only possesses the advantages of the gravity system, but, in addition, is of much higher electro-motive force. The couple may be of zinc and copper, but that shown is preferable, and is of zinc with a large carbon plate. The upper side of the latter is enlarged by numerous studs to give increased surface. In putting up a battery of this kind the glass jars are to be filled, just high enough to cover the zinc plates, with a solution of either an alkaline sulphate, preferably that of magnesia (one part in four parts of water), or an alkaline chloride, preferably that of ammonium (one part in five parts of water), each cell requiring about forty-five fluidounces. To these solutions may be added from five to ten per cent. of hydrochloric acid, which lessens the internal resistance, but causes some local action on the zincs. The depolarization is effected by means of a "sulpho-chromic salt" made and furnished by this company. Of this salt, in which sulphuric acid has been caused to combine with chromic acid in an amorpho-crystalline state, equal portions are dropped into the several glass tubes, whereupon the carbon cathodes soon become covered with a dense stratum of depolarizing liquid, which maintains therewith the energy of the apparatus, and it is only necessary to renew the supply at intervals.

The electro-motive force of a cell is about 1.95 volts. Its strength of current is:

With a solution of	sulphate of magnesia.....	3	ampères.
" "	chloride of sodium.....	5.5	"
" "	ammonium..	6	"

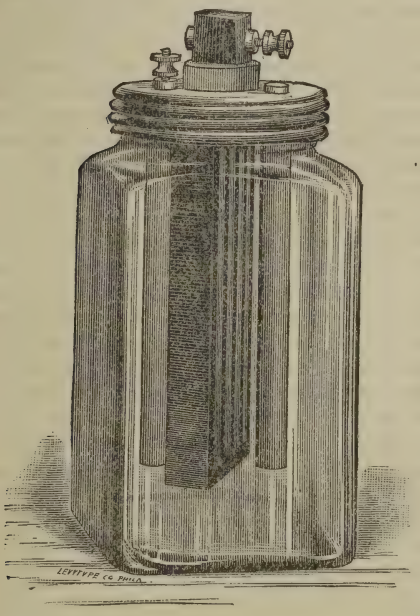
An addition of ten per cent. of hydrochloric acid increases the strength of current of a cell:

With a solution of	sulphate of magnesia to	5.25	ampères.
" "	chloride of sodium.....	6.6	"
" "	ammonium..	7	"

For ordinary use in the office the addition of the acid is not required, and the depolarizing material is added from time to time according to the demand required of the battery, and no interruption is caused by so doing. The zincs may remain in the liquid, unless the battery is unused for long periods, when they should be raised and supported by pins through the rods which are fitted for that purpose.

The Acid Gravity Battery has proved of excellent service in its application to electro-magnetic dental mallets, which are satisfactorily operated by four cells. Its efficiency and great convenience render it equally well suited for surgical and dental glow-lights, for cautery (from four to six cells), and there is no voltaic apparatus better adapted to the wants of a chemical or physical laboratory.

Another modified cell is that suitable for portable batteries and for intermittent work on circuits of high resistance. In the Leclanché, once the electrolite is ex-



hausted, the cell must be replenished at the factory, but this can be renewed by the owner by soaking the cathodes in hot water and adding the depolarizing salt. The initial electro-motive force is 1.6 volts, and a current strength of 2.8 ampères per cell. The carbon cathodes are slotted to increase their surface, and double anodes are employed, connected by the zinc cover, which screws down tightly to prevent evaporation and efflorescence. The element is very constant, and does not run down so rapidly as the ordinary ammonium chloride cells. The finish, as shown by the cut, is excellent. The measurements were made by Professor Dolbear, and his results have been verified by the writer.

STATIC ELECTRIC MACHINES.

The Toepler-Holtz machine, made by Messrs. James W. Queen & Co., of this city, noticed in a recent review,* has been still further improved, and in stability, promptness of working, and ready adaptation to direct and the so-called "secondary induction discharge," it is believed to be unequalled by any other for either medical or experimental work.

In muggy or very hot weather the best static-electric machines are difficult to operate satisfactorily, and to overcome this defect various methods are employed. The better way to insure dry plates is to isolate the machine from the surrounding atmosphere, and Messrs. Queen & Co. have devised an air-tight glass case which serves the purpose admirably. The operation of the revolving plates may be maintained either by the crank with hand-power or by the treadle and spring. Beneath the case compartments are arranged to hold rheophores and chains or other accessories, and, if desired, a vessel of anhydrous sulphuric acid or chloride of calcium may be placed within the case to dry the contained air thoroughly.

The case can be fitted to any Toepler-Holtz machine, and thus arranged static electricity is controlled as readily as is the Ruhmkorff coil.

INTERRUPTER, COMBINER, AND CURRENT-REVERSER.

Dr. De Watteville, of London, has written to say that the switch illustrated in our review of July 10 last was introduced by himself several years ago. We take pleasure in correcting the unavoidable error on our part in reference to its invention, as the English attachment had not been seen at the date of writing, and we had inadvertently overlooked the illustration in the second edition of the distinguished author's classical work on medical and surgical electricity.

246 North Twentieth Street.

For Leucorrhœa.—

℞ Potassii chloratis, ℥iij;
Tinct. opii, f℥iij;
Aq. picis liq., f℥viij. M.

Sig.—One to three teaspoonfuls in a quart of warm water, to be injected morning and evening.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CASES FROM DR. MORTON'S CLINIC,

Held October 23, 1886.

RUPTURE OF LONG TENDON OF THE BICEPS MUSCLE, DUE TO MUSCULAR EFFORT—SUTURE, AND SUCCESSFUL RESULT—ANTISEPTIC APPLIANCES.

THE patient is a laboring-man, about 50 years of age, who came here three days ago, with a rupture of the long tendon of the biceps muscle of the right arm. He was at work in a pit ten feet in depth, standing at the bottom and throwing shovelfuls of dirt out of the top, when suddenly he experienced a sharp pain in his shoulder and was unable to continue at his work. I found upon examination of his arm that the long tendon of the biceps had been ruptured. The muscle was firmly contracted and in a state of spasm. I cut down upon the muscle and found its tendon coiled up upon it like a worm. I cut off the frayed end of the tendon, and, replacing it in a deep groove that I had cut in the deltoid (which I had exposed to the acromion), I stitched it deeply into the tissues of this muscle with catgut interrupted sutures. The usual dressings were applied, and the arm kept in a sling. That was sixteen days ago. The dressings have not been disturbed since; they will now be removed. You see the line of the incision, which has perfectly united. Some remnants of catgut sutures are lying upon the dressings, which are perfectly dry. Although the wound has healed, we will not allow the man to use his arm yet; he should not go to work again for another fortnight, but there is no need of keeping him in the hospital. He can report at the Out-Patient Department, and carry his arm in a sling until the newly-united tendon has united firmly in its new location.

Two cases came in on last Thursday afternoon which I regard as crucial tests of aseptic surgery: they will now be brought before you.

GUN-SHOT WOUND OF THE POPLITEAL REGION.

The first man was shot thirty hours before his admission, while in the mining regions, and received a wound in the popliteal space, which at the time was accompanied by excessive hemorrhage: a pistol-bullet had not been removed from the wound. Upon examination I came to the conclusion that the ball must have injured the important deep structures, since the wound was directly in line with the large blood-vessels and nerves, and that it had possibly entered the joint. Sensation in the parts below was preserved, but there was no pulsation in the anterior tibial artery or its branches in the foot.

With antiseptic precautions, I opened the popliteal region, and found the ball lying some distance beyond the artery, it having also injured the knee-joint. The bullet, which was from a Smith & Wesson revolver of .32 calibre, had completely divided the popliteal artery, and had wounded but had not opened the accompanying veins. The divided ends of the torn artery were carefully isolated; the proximal end was filled with clot, the other end was patulous. Both ends were securely tied, in order to prevent secondary hemorrhage. I used catgut ligatures, which were cut short, and the wound was then closed in the usual way and a rubber drainage-tube was inserted. The patient, since the operation, has been perfectly comfortable. An injury of this kind, involving a divided main artery and a joint involved, has always been considered very grave, and one which under other forms of treatment might, and probably would, demand an amputation. I need not now stop to point out the great difference between the results of treatment by former methods in these grave cases and those which we have obtained here by strict antisepsis.

DISLOCATION OF THE KNEE, WITH LACERATION.

The second case is one in which the knee-joint was entirely exposed by a fall, which ruptured the old inflammatory adhesions that had been thrown out in nature's attempt to unite by new tissue a ruptured quadriceps more than a year ago. The skin and deep tissues were so torn as to expose the condyles of the femur and the articular surface of the tibia, the lateral and crucial ligaments were torn, and the wound of the soft parts around the joint was so extensive that the leg was held only by a posterior flap, in which, however, the vessels and nerves were preserved intact. I made lateral vertical incisions upward four inches in length on either side, just as if I were going to perform an amputation, and so

was enabled to lift up the tissues and to clean out the knee-joint and adjacent wound with a douche of one to one thousand solution of corrosive sublimate: all clots were carefully removed, and the wound-surfaces thoroughly curetted. I then brought the parts together with about twenty interrupted catgut stitches, and dressed the wound antiseptically as already described. His temperature this morning, forty hours after the operation, is only $100\frac{1}{5}°$, and his general condition is good. When you consider the character of the case,—that he was in a bad condition, that he has been a drinking man, and that he was under the influence of liquor when he received the injury,—I think you will agree with me that the result thus far has been remarkable. The object of the treatment was to seal up the joint and to prevent the occurrence of irritation and suppuration by the exclusion of all micro-organisms.

The next case is one of contusion of the upper part of the thigh, with a very large hæmatocele, just above the knee, of one week's duration. I shave the part thoroughly, wash it clean with bichloride solution, and cut open this sac from one end to the other, and my incision is five inches in length. I turn out the clot and wash the wound with a one to one thousand solution of corrosive sublimate: with a sharp spoon I am now scraping the walls of the cavity, so as to remove all disorganized shreds of tissue and blood-clots. This having been done, I unite the edges of my incision with interrupted catgut sutures, and apply a compress of gauze wet with the same solution. Iodoform is thickly dusted over the wound, and absorbent cotton, previously washed with the mercuric-chloride solution, is next applied, and retained in place with a bandage wet in the chloride solution. A few strands of catgut ligature are placed in one angle of the wound so as to admit of drainage, and a straight splint is placed on the back of the limb to insure rest.

TEALE AMPUTATION OF THE LEG FOR DEFORMITY.

The next case is a man from the mining regions upon whom I will perform a Teale amputation. About a year ago he was injured by a falling mass of coal, which crushed his right heel. This accident was followed by prolonged suppuration and ulceration. As a result there is contraction of the plantar fascia and of the gastrocnemius muscle to such an extent that he has an acquired talipes equinus; the foot is permanently extended, so that he walks upon the base of the big toe; anchylosis of the tarsus and ankle-joint has taken place; the sole of the foot is covered only by a thin skin or scar-tissue, which is adherent to the bone beneath.

The only remedy for this state of affairs is amputation and an artificial limb.

It is always best before making a Teale operation to measure carefully the size of the flaps and mark their outlines with iodine or the point of the knife. You should never trust simply to your eye.

Proceeding now to the operation, the limb is first washed with soap and water and carefully shaved. It is next bathed with the one to one thousand solution, and towels wet with the same are placed around the limb above and below the line of operation. The hands of the surgeon and assistants are also disinfected, likewise the Esmarch bandage. The knives and other instruments for the operation have been boiled in water, and are kept in a tray under a weak solution of carbolic acid, because the corrosive chloride would act upon the steel and dull them.

The limb at the point of amputation measures ten inches exactly. The long flap then will be five inches in length and breadth. I will take it from the outside external aspect of the limb, because there is more healthy tissue here. The short flap I will now mark one and one-fourth inches long and five in breadth. All the soft parts help to make up the flaps, which are now separated from the bones and the tibia and fibula divided; the wound is washed with the same solution of bichloride, and the vessels are secured with catgut ligatures, which are cut short. Some strands of catgut, instead of rubber tubes, are placed in the lower angle of the wound, and the flaps are brought together with catgut sutures.

The same dressing, of bichloride gauze thickly dusted with iodoform, is applied as in our other cases,—first having placed a strip of silk protective over the sutures, then a layer of absorbent cotton, which has also been treated with the one to one thousand corrosive-sublimate solution; the dressings are kept in place with a wet bichloride bandage. Unless something unusual occurs, indicated by a rise in temper-

ature (which shall be carefully recorded morning and evening each day), this dressing shall not be disturbed for three weeks. I will then bring him before you again and show you the result.

In case a rise of temperature occurs, first find out if this is due to some intercurrent malady. In September last, forty-eight hours after a serious operation, the temperature of one of my patients rose to 103°. An examination showed a sharp attack of diphtheritic tonsillitis, from which the patient soon recovered, but which in no wise affected the wound, which was not opened for several weeks, when it was found quite united, as in those you have seen.

ANTISEPTIC APPLIANCES.

My son, Dr. Thomas S. K. Morton, Senior Resident Surgeon at the Pennsylvania Hospital, has presented me with the following details, which I regard as so important that I have concluded to add them to the report of my lecture.

The antiseptic *dressing* is only the ending of a series of manipulations upon, and applications to, a part before, during, and after an operation. *Per se*, it is almost valueless unless all the necessary details leading up to its application are thoroughly carried out.

Entirely disregarding theory, what is aimed at is to have the field of an operation, upon its completion, free from any substance which can become an irritant or develop fermentation; then to apply some form of dressing which will entirely prevent access of such material to the wound.

Since its first introduction by Lister, the term antiseptic has been made to embrace every procedure likely to prevent such wound-complication, and its range of applicability is rapidly on the increase.

No one dressing or system of antisepsis can yet be spoken of as best: their name is almost legion. The object which it is essential that we shall keep in view is the antiseptic principle: its details of application may be varied.

Hospitals are the only places where comparative tests of such details can be made, and I present below a list of those in present use in the Pennsylvania Hospital. These are the result of much comparative work, experimentation, and investigation, and it is hard to conceive how our wounds could do better than they do.

Cleansing of Parts. — Carefully shave the field of operation and its surroundings; hair grows everywhere except on the palms and soles,—an exception to the above rule,—and is very tenacious of dirt. Then rub well with turpentine or ether, then soap, and a final wash with the one to one thousand bichloride solution. Special pains should be taken to cleanse such parts as the ear, umbilicus, toes, axilla, and groin. If the operation be in the auricular region, wash the pinna of the ear as thoroughly as possible, sprinkle the canal full of iodoform, and put in a small wad of bichloride cotton on top; the cotton, if it become soiled, can be removed before the dressing is applied.

For special occasions, the operative field and its surroundings can be thus treated beforehand and then wrapped in either an antiseptic dressing or in towels wrung out of one to one thousand sublimate solution. A simple irrigation of one to one thousand solution will only be required at the time of operation after this preliminary cleansing. An oil-cloth should be placed under the part to be operated upon and wet with the one to one thousand douche. So also towels wrung out of the same solution should surround the field and cover any part which the operator is liable to touch or lay instruments upon.

Arrest of Hemorrhage. — Great care must be exercised in the ligation of bleeding points. Invariably the catgut ligature should be used for this purpose, unless the vessels are very near the surface and can be stopped by running a stitch through or under them. The catgut which we use is procured either from wholesale dealers in musical supplies, or from importers. Five sizes, running from the finest made to the largest cello string, are all that can be needed for any surgical purpose. To prepare this material properly, the commercial gut should be soaked in oil of juniper for forty-eight hours, washed in alcohol, and stored in the same. The oil of juniper removes the animal oil, so that it becomes quickly pliable in aqueous solution, antiseptic, and will be absorbed in from seven to ten days, according to size.

Stronger and more durable catgut can be made, if desired, by means of chromic acid. The formula is as follows: Take twenty parts of water, one part of carbolic acid, $\frac{1}{200}$ part of chromic acid, and to this mixture add one part of catgut as prepared above. Let it stand for forty-eight

hours, wash in alcohol, and preserve in the same. This gut, according to size, will resist absorption from ten to thirty days. In tying catgut, all difficulty will be overcome if the first knot be made a surgeon's knot.

Drainage.—If care has been taken to arrest bleeding properly, there should be very little material poured into even the largest wounds after their closure, for bichloride, unlike carbolic acid, produces very little tendency in a wound to ooze.

In a properly-managed wound, all possible discharge should be over by, at most, the third day. Various means are employed to accomplish the drainage of this actual, or possible, discharge of bloody serum into wounds. Principal among these are bunches of fine catgut and perforated tubes of rubber, decalcified bone, or parchment. I cannot yet speak with positiveness of more than the first two mentioned. The latter and others are still under trial. Catgut in hanks of from three to twelve strands can be depended upon to drain most wounds which are expected to heal by primary union, even the largest. But if the surgeon has not sufficient confidence in it, the rubber drains may be used, but should be early withdrawn. This is their worst objection, as to accomplish it the whole dressing has to be removed at the most critical time in a wound's healing. Catgut will not, as a rule, drain pus, as it operates by capillarity: hence tubes must be used for the drainage of antiseptically-treated ineradicable abscesses, etc.

The catgut drains, which are made up of fine threads, are absorbed in from seven to ten days.

The rubber tubes are kept in three-per-cent. carbolic acid solution.

Irrigation.—This is kept up from time to time during an operation where antisepsis is possible; it will do no harm in any operation, and probably some good where cleanliness is impossible. It is accomplished by a small stream of the one to two thousand solution directed from a vaginal, Thudichum, or other douche apparatus.

One to two thousand is our standard solution for this purpose, and multiplications or divisions of that strength are made up for special occasion. For example: one to two thousand for wounds filled with dirt; one to twenty-five hundred for poison-wounds, such as dog-bites; one to five thousand or ten thousand for abdominal work. Of course, the latter two are to be washed out by much weaker solutions or by distilled water *ad libitum*.

Sponges are used but once, and then destroyed. We buy them in twenty-five-pound bales, and bleach and purify them by the following process.

Soak in ten-per-cent. hydrochloric acid solution for twenty-four hours, wash thoroughly, and place for an hour in a solution of permanganate of potash, one hundred and eighty grains to five pints of water. Take out, squeeze, and drop into this mixture: dissolve ten ounces hyposulphite of sodium in sixty-eight ounces of water, and filter. To this add five ounces hydrochloric acid. Put in sponges, and leave until thoroughly bleached; then wash them *most thoroughly*, and store in one to one thousand of corrosive sublimate. When ready for use, they cost about three-fourths of a cent each.

Instruments and Apparatus.—Our instruments are invariably boiled after an operation, and, if possible, before. When the latter is done, they can safely be used directly from the water as it cools. Usually they are kept immersed in a three-per-cent. solution of carbolic acid.

Needles, also pins liable to penetrate deeply into the dressings, should be kept in three-per-cent. solution of carbolic acid in glycerin. Instruments can be permanently kept in this solution without damage. Nail-brush and soap should be used on all instruments both before and after operation. All apparatus, such as tourniquets, etc., which may come in contact with the wound or its unprotected vicinity must be previously soaked in either corrosive sublimate or carbolic solution.

Closure of Wound.—The details of this usually neglected proceeding are of great importance. Wash thoroughly with the mercury solution. Remove the larger clots; the smaller will organize or be absorbed. Adjust an appropriate drain, and suture with catgut of the proper absorbability. If the wound be deep, it should be sewn structure to structure from the bottom upward. The skin and immediately subcutaneous tissues sew with very closely placed interrupted or continuous sutures of the same material, taking care to leave sufficient room at the drain-exit for its proper working.

Protective is a substance employed to

keep the irritating dressing from direct contact with the newly-formed repair-cells. It is simply fine oiled silk, coated with a preparation of copal varnish, dextrine, and carbolic acid. This is merely to prevent its shedding water, etc., as ordinary oiled silk does. It is laid in a narrow strip along the suture-line, overlapping it about one-half inch on either side. It is of much more importance where the edges of the wound do not approximate. In that case, if the area to be covered is large, a series of narrow strips is better than one large piece, as it allows of immediate drainage into the antiseptic materials of the dressing. The protective should cover in the ends of the catgut drains, so as to keep them moist and in working order. In removal of the dressing it prevents drawing upon the stitches, etc. It is kept in air-tight glass jars and dry. When wanted, cut off a sufficient amount and place in corrosive or carbolic solution.*

Dressings.—Our principal dressing consists of the gauze of Lister (cheese-cloth impregnated with this mixture while hot: carbolic acid, one part; resin and paraffine, each four parts) wrung out of one to one thousand bichloride solution, in which it is kept. It is cut so as to overlap the wound considerably, and its skin-surface thickly covered with iodoform sprinkled on with a salt- or sugar-duster. Bandages which are to be put on wet with this solution are made from the same gauze. In a small wound eight layers of the moist gauze bound on with a gauze or ordinary roller is all that will be required. If the wound be large or liable to ooze, a considerable pad of bichloride (one to one thousand) dry absorbent cotton is superimposed, and the gauze-bandage placed over all.

TRANSLATIONS.

COTO BARK AND COTOINE IN DIARRHŒA.—In a note read before the Société de Thérapeutique, Paris, Dr. H. Huchard reported his experience in the use of cotoine in diarrhœa. Coto bark was introduced into Europe in 1873 from Bolivia, where it had been employed in gout and rheumatism, but especially in the treatment of diarrhœa. Jobst, of Stuttgart, in 1875 succeeded in isolating the active principle *cotoine*, and from an allied species he obtained a similar one, to which he applied the name of *paracotoine*. Cotoine crystallizes in yellow four-sided needles, resembling commercial gallic acid. It melts at 130°, is soluble in warm water, chloroform, ether, alcohol, and sulphide of carbon, and slightly soluble in cold water, petroleum, and benzine. It is likewise dissolved by alkalies, yielding a yellow color; with sulphuric acid it is yellowish brown, and with concentrated nitric acid strikes a blood-red color. This reaction enables it to be recognized in the urine in from seven to ten hours after its administration. Paracotoine is less active than cotoine, is scarcely soluble in water, and does not give the color-reaction with nitric acid. Coto bark also contains, according to Jobst and Hesse, other principles,—*oxyleucotoine*, *leucotoine*, and *hydrocotoine*, the therapeutic effects of which are less marked than those of cotoine.

The physiological action of cotoine has been studied by Pibram, Benkart, and Albertoni. It has antiseptic and antiputrefactive properties; it stimulates appetite and gastric digestion, and does not cause constipation. It was given in relatively large (1.50 G.) doses to rabbits and guinea-pigs without producing marked toxic effects. The most decided property of cotoine is the dilatation of the vessels of the intestinal walls (Albertoni) following its administration, and the consequent improvement in nutrition of the mucous membrane.

Therapeutically, cotoine has been found valuable in diarrhœas of all kinds. Even in typhoid fever and in cholera it has been employed with some success. Huchard has administered it hypodermically, as recommended by Bourneville and Bricon, but with unsatisfactory result. He prefers the powders by the mouth, containing twenty centigrammes, of which two or three should be given daily.

The results obtained in twenty-one cases were as follows. In ten cases of diarrhœa with tuberculosis (three of which had intestinal ulceration), in eight of catarrhal diarrhœa, and in three of arthritic diarrhœa of four months' standing, the cotoine was given as directed, and with success in all except two cases of tuberculosis. Fronmüller, out of ninety-three cases of diarrhœa following typhoid fever, noted

* At my suggestion, Mr. Geo. J. McKelway, 1412 Chestnut Street, will furnish complete sets of these dressings, all ready for use, in a convenient case.

only nine cases of failure. Parsons, Burney Yeo, and Rohrer have also used it with remarkable success in infantile diarrhœas. These results are sufficient to assure cotoine a high position in therapeutics.—*Bulletin Générale de Thérapeutique*, August 30.

Nocturnal Incontinence of Urine in Children.—Dr. Picard has found prompt results follow the application of faradism, one pole being applied to the perineum, the other over the abdomen in the hypogastric region, or in the rectum. In some cases it was necessary to introduce one of the poles into the urethra, the other into the anus. The current was passed for from two to five minutes, either daily or every second day. Internally, iron may be given in combination with ergot or strychnine. Hydrotherapy is a powerful tonic, but should be administered with caution. Sea-water baths are especially useful where the patients are lymphatic or scrofulous, and sulphur-baths for nervous children. If the incontinence be associated with or dependent upon vesical inflammation, the injection of nitrate of silver (one or two grains to the ounce of water) may be practised with advantage. When the urine is decidedly acid or of unusual density, diluent or alkaline solutions (sodium bicarbonate) may be drunk. The child should be taught to extend the time between the acts of urination during the day, so as to reduce the sensibility of the bladder and train it to tolerate the presence of urine for a longer period. Of course, due attention is to be given to eating and drinking, especially at the evening meal. In some cases moral treatment, in the shape of corporal punishment, is very effective, and gives a better result than medicine.—*Le Progrès Médical.*

[Before recommending the rod, the physician should ascertain whether or not the cause may not be beyond the child's control, as, for instance, where it is due to albuminuria, diabetes, or ascarides.—Ed. P. M. T.]

Massage in Certain Fractures preferred to Immobilization.—In a communication recently read before the Société Médicale des Hôpitaux, M. Just Lucas-Championnière gave expression to the following conclusions :

Immobility in the treatment of some fractures is habitually much too prolonged and much too general.

In intra- and para-articular fractures it is accompanied by decided dangers.

Except in cases of great primary displacement, fractures of the radius and fibula do not need fixed dressings.

Massage relieves pain and favors repair.

Passive motion prevents stiff joints and subsequent lameness or pain.

Massage properly conducted acts well from the beginning, and can be continued in conjunction with other treatment. By its means the length of treatment is materially reduced.

Fractures in the vicinity of large joints are less suited for primitive massage, but they unite very well without immobilization, and passive motion and secondary massage are very successful in hastening union.

Fractures complicated with wounds of the soft parts treated in the same manner have furnished results which the old treatment, in the author's experience, had never afforded.

Finally, the complications, neuralgic pains, and crippled or weak limbs are due generally to the immobilization of neighboring joints: in these cases no treatment can compare with massage for the removal of pain or the restoration of function.—*Revue de Thérapeutique Méd.-Chir.*, No. 15.

Warts cured by Internal Medication.—M. Colrat reported a series of cases to the Lyons Society of Medical Sciences, illustrating the treatment of warts by magnesia taken internally. Several children to whom ten to fifteen centigrammes (two to two and a half grains) twice a day were administered were promptly cured; others proved refractory for several months; while others still were absolutely unaffected by the treatment. Even large warts (not polypiform) have fallen off under this medication. The well-known tendency to contagion—*i.e.*, from the hand to the face—has been attributed to a specific cause; and M. Cornil has found a microbe in tissue of the little growth. M. Aubert reported the case of a woman whose face was covered with warts, though none were found on her hands. She recovered entirely after the administration of magnesium sulphate—six grammes daily—at the end of six weeks. M. Roux mentioned a case having large and numerous warts cured in fifteen days by the administration of fifty centigrammes daily.—*La France Médicale*, October 16.

MEDICAL TIMES.

PHILADELPHIA, NOVEMBER 13, 1886.

EDITORIAL.

THE MALARIAL BODIES OF LAVERAN.

THE observations of Laveran on the presence of certain organisms in the blood of patients suffering with malaria are being confirmed on all sides. The Italian observers Marchiafava, Celli, and Golgi, whose opportunities for the study of paludism in all forms are unequalled, have found essentially the same changes, and in this country Councilman, of Baltimore, has determined their presence in all cases of malaria examined by him.

At the conversational meeting of the Pathological Society of Philadelphia, November 3, Dr. Osler communicated the result of a study of the blood in over fifty cases of ague, and he too finds the bodies described by Laveran to be constant features. At the Washington meeting of the Association of American Physicians, if we remember rightly, Dr. Osler expressed himself rather doubtfully as to the nature of the bodies he had seen, but further study has evidently convinced him of their parasitic character.

He described the bodies as occurring both inside the red corpuscles and free in the plasma. The intra-cellular form appears as either a hyaline or a darkly-pigmented body, filling one-third or one-half of the corpuscle, and undergoes slow amœboid changes. The hæmoglobin of the corpuscle is gradually destroyed by the organism, and the stroma becomes pale and finally colorless. There seems to be no doubt whatever about the amœboid character of these movements, which are readily followed with a high-power objective. The forms occurring outside the corpuscle are still more remarkable. These are (1) small, circular, pigmented bodies, (2) curious crescent-shaped organisms, and (3) an extraordinary flagellate body resembling an infusorian. The pigmented crescents have been noted by all observers, and are much more readily seen than the amœboid bodies. They do not occur so frequently, and apparently only in the later stages of the disease. The flagellate form, also pigmented, is still less common, and was seen by the lecturer in only six cases. The movement of the flagella is very active, so that it brushes away the red corpuscles in its vicinity.

The relation of these forms to one another is still doubtful, though they probably represent phases of development of the same organism. He also described a segmentation in certain forms, which, if followed, may give a clue to the life-history. In the absence of fuller details, it seems impossible at present to classify the organism, though its affinities are evidently with the flagellate infusoria. Marchiafava and Celli have suggested for it the name *plasmodium malariæ*.

Dr. Osler did not seem prepared to give a positive opinion as to their causal connection with the disease. They do not, like the spirillum of relapsing fever, occur only in the paroxysm, but appear equally abundant in many cases both before it and after. The acute cases, however, seem to have the pigmented bodies in the corpuscles, while the more chronic forms have the crescents. Perhaps the most important point at present with reference to these bodies is the valuable aid they afford in diagnosis. The cases mentioned by the lecturer, and also by Dr. Musser, in the discussion, illustrate the importance which these bodies may hereafter assume in the detection of doubtful cases.

Another most interesting feature is the influence of quinine in reducing their number in the blood and finally destroying

them altogether. To us this seems one of the strongest arguments in favor of the causal relationship of these bodies and the disease. It is well for us, however, to be cautious. We have not yet forgotten Salisbury's palmella or Klebs's bacillus malariæ. These malarial bodies of Laveran, however, are readily demonstrated, and the studies of five or six independent observers in different parts of the world practically agree, so that we may reasonably hope that at last we have something tangible, which further observations will show to be intimately connected with the production of the disease.

PRACTICAL ASEPSIS AT THE PENNSYLVANIA HOSPITAL.

IN a general way, every practical surgeon has become familiar with the fact that the introduction of Listerism—by which we understand the application of means with the definite purpose in view of preventing sepsis in wounds—has within the last ten years given a great impetus to operative surgery. Operations within the peritoneal cavity, and upon the brain, which defied the skill of a preceding generation of surgeons, are now not only rendered legitimate, but also are performed successfully almost daily. The advantages of antisepsis in wound-treatment have been so fully demonstrated that several European governments have included packets of antiseptic material in the individual military outfit, in order that the soldier may carry with him upon the battle-field appliances for the primary dressing of wounds.

Notwithstanding the fact that proofs of the superiority of the new and only scientific methods over the old have accumulated until they appear logically irresistible, we find that many surgeons still conduct their practice, both hospital and private, according to the routine and empirical methods of a score of years ago. Others apply them in part or inefficiently, and therefore only invite failure and bring discredit upon the system by their neglect.

At the Pennsylvania Hospital during the past six months it is claimed that the aseptic method of wound-treatment has been carried out systematically and completely in the service of Dr. Morton. Some of the results we have already laid before our readers. We do not exaggerate in making the statement that the introduction of the aseptic system of dressings has revolutionized the system of wound-treatment in an institution which has always been noted for its strict cleanliness and successful surgery. Erysipelas and septicæmia have been banished from the wards, and even suppuration is now rarely permitted to occur. Some of the results may be mentioned for purposes of comparison. Amputations, as the rule, are dressed only once, and retain the original dressing until the expiration of three weeks: elevation of temperature rarely occurs, even after grave operations. In a lacerated wound of the knee, opening the joint and tearing the ligaments and skin, the dressing was not removed until the seventeenth day; no suppuration had occurred, the temperature remained about normal, and the wound was found perfectly healed upon removing the dressings. Two cases of compound depressed fracture of the skull recovered in a few days as though from a simple wound of the scalp. A ruptured tendon of the biceps was replaced and stitched deep within the deltoid muscle, and the wound united by first intention, with restoration of function. An excision of the cuboid bone for distortion of joint in a case of club-foot was equally successful. These results are simply perfect. The details of the method of wound-treatment which accomplishes such results must be of the greatest interest to the profession, and we therefore are glad to be able to give them, through the courtesy of Dr. Morton, on another page.

Dr. Morton very justly says that there may be many other ways of securing immunity from wound-infection, and that he does not insist upon the methods practised by him as being the best for all, although he has found them the best for himself; but he desires to lay especial stress upon the fact that, unless means are adopted which secure complete asepsis, Listerism is not practised. Partial antisepsis is not antisepsis at all.

The question is pertinent concerning the possible medico-legal complications arising out of the new surgery. If wounds made in the course of major or minor surgical operations can be kept absolutely aseptic, and the means are well known and open for all to adopt by which this end may be attained, what responsibility will attach to a surgeon who neglects to adopt antiseptic precautions, if his patient suffer subsequently with suppuration or septicæmia? A few suits for malpractice would have the effect of stimulating the interest of surgeons in the new surgery. Will they be needed?

SOCIAL AND UNSOCIAL MEDICAL SOCIETIES.

AT the meetings of the American Medical Association and other national organizations the Committees on Entertainment have important functions, and the success of the meetings is largely dependent upon the proper performance of their duties. It would be a consummation devoutly to be wished that every medical organization would appoint a standing committee on the "Promotion of Sociability among its Members." We have attended meetings which were quite the reverse of social in their tone, and we feel sure that the systematic cultivation of the amenities under the direction of an active committee would largely increase the attendance at our medical societies.

Some of the prominent medical practitioners of Baltimore, at the suggestion of Dr. George H. Rohé, have organized a medical society there which holds monthly social meetings, at which a good dinner is the principal subject of discussion. It is appropriately called the "Flint Club," in honor of the late Professor Austin Flint, who was eminently social in his tastes. By such means good fellowship, friendly intercourse, and mutual regard can certainly be advanced in the profession. It is suggested that Flint Clubs might well be instituted in other cities where similar social medical organizations either do not exist or are confined to the alumni of a particular school, or are otherwise exclusive to the general practitioner.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

THE French Surgical Congress.—The second annual session of this new institution was opened on the 18th instant, under the Presidency of Professor Ollier, of Lyons, and the Vice-Presidency of Professor Verneuil, of Paris, who will preside next year. The meetings are held in the grand amphitheatre of the Faculty of Medicine, which is fitted up with considerable taste under the directions of Professor Pozzi, who is the General Secretary to the Congress. On opening this session, Dr. Ollier said that the young Association, now in its second year, would be sure to meet with great success, which was already in fact guaranteed to it by the large number that have already united with it, not only French surgeons, but also those of foreign countries. The International Congresses, he said, give splendid results, notwithstanding the difficulties involved by the diversity of languages: what, then, may not be hoped from a Congress using the French language only? In closing, he insisted on the necessity of division of work in our scientific medical studies, and he said that specialties must continue to be produced, and that they should form associations in order to elaborate and concentrate their ideas.

The first paper read was that of Dr. J. Reverdin, of Geneva, "On Accidents consecuive to Extirpation of the Thyroid Gland."

M. Thiriar, of Brussels, followed with "The Importance of daily determining the Quan-

tity of Urea in Abdominal Surgery." He found that this gave very important results in diagnosis, and advised certain precautions in its use to obtain success:

1. The analysis should always be made of a sample of the total amount of urine passed in the twenty-four hours. It should also be repeated several times, and for a number of days: at least ten days' results must be taken for an average.

2. The patient ought not to be suffering with tuberculosis, albuminuria, or fever.

As a rule, an adult will excrete twelve to twenty-four grammes of urea in the twenty-four hours. In benign tumors the average was fifteen to twenty-five grammes.

Observation I.—Patient, 42 years of age, whose doctor gave a diagnosis of ovarian cystoma, but the operator was inclined to think it a tumor of the spleen. The urea excreted daily was eighteen grammes ninety-one centigrammes, and the white globules were only one to twenty red ones. He thereupon gave a diagnosis of hypertrophy of the spleen, which was confirmed after operation.

Observation II. was also a splenic tumor, which this time had been diagnosticated as cancer of the omentum. The average of urea daily was nineteen grammes forty-three centigrammes. Operation once more confirmed the diagnosis of tumor of the spleen.

In these tumors, then, the quantity daily excreted was *over* twelve grammes. It is quite different in malignant tumors, for here the cellular nutrition is rapidly interfered with, and the result is a relative incapacity to form urea. Cases to prove this were the following:

Observation III.—A woman showing signs of an ovarian cyst. Upon examination of the urine it revealed only four grammes of urea. This put him on his guard, and he first made a puncture, which brought out a greenish liquid and proved that it was a case of cancer of the omentum.

Observation IV.—A Brussels lady of 45, presenting a uterine tumor. Analysis of the urine revealed only 8.42 grammes of urea. Operation proved it to be a malignant neoplasm.

Several other cases were reported, all tending to prove the great utility of determining the quantity of urea eliminated in diagnosticating abdominal tumors. In benign tumors the daily amount he had always found *over* twelve grammes, and in the malignant forms it was always *under* the twelve grammes.

Professor Guyon, of Paris, followed with "Indications and Contra-indications for Rapid Lithotrity."

The second morning was taken up with M. Vaslin's paper on "The Nature and Treatment of Tetanus," in the discussion of which a large number of the surgeons present took part. It was followed in the afternoon by a number of "questions diverses," among which was that of "Vaginal Hysterectomy," by Professor Richelot, the eminent surgeon, and the chief editor of the journal *L'Union Médicale*. Dr. Richelot said, "This operation is still young in France, as I can find only thirty cases in which it was performed, and ten of them were those upon which I myself operated. The operation is divided into three parts,—isolation of the uterus, treatment of the broad ligament, and treatment of the wound itself. The treatment of the broad ligament is the delicate part of it, owing to the difficulty that exists in applying ligatures, and the hemorrhage that results is the principal cause of death from the operation. I have advised for a long time the application of 'forcipressure' in these cases, and this method has been found favorable to success in these operations. There has been a great deal of discussion on the question of priority in the use of forceps-pressure, but I will not now enter on that debate, as it seems to me to be useless. I will simply say that the method has found an exceptionally happy application in the operation of vaginal hysterectomy. In regard to the treatment of the wound, we find it now entirely changed by the use of the forceps, as we no longer have to use a drain, for they assure the outflow of all liquids; nor do we need to use sutures, as the forceps are long enough to extend beyond the external opening of the vagina. This operation is, in fact, so easy of performance, and so safe, that I do not hesitate to advise it in all cases of cancer of the uterus that can be operated upon. Nothing should be left to the form of ablation called 'susvaginal.' If it can cure cancer sometimes, surely the more radical operation of vaginal hysterectomy, as now performed, is much better and more thorough. In fact, I think the operation is sufficiently benign to advise it not only in uterine carcinoma, but also in cases of tumors that are not of a malignant nature, such as uterine fibroma that are very painful and by loss of blood threaten to destroy the patient.

"I would also advise operation by this means upon those forms of prolapsus and uterine retroversions that are rebellious to other treatment, and I think that one may go as far as to use this operation in some cases of uterine inversion and in utero-ovarian neuralgia."

M. Duplouy, of Rochefort, M. J. Boekel, of Strasburg, M. Tédenat, of Montpellier, and M. Demons, of Bordeaux, all spoke in favor of the operation.

When M. Péan, of Paris, asked to speak, there arose considerable excitement, for it was known that there had been several letters published between Drs. Richelot and Péan on the subject of priority in using forceps-pressure, and it was understood that M. Péan would claim the entire invention and use of artery-forceps. The facts are that he has for some years been in the habit of using all sorts of

artery-forceps in his surgical operations at the St. Louis Hospital, but it must be admitted that M. Richelot deserves the credit of using them with such great benefit in the above-mentioned operation.

Dr. Péan claimed that he had for a long time advised preventive pinching of vessels not only in the abdomen, but elsewhere in the body, and spoke of his operations in the mouth by the aid of artery-forceps, going so far as even to compress the femoral, and he claimed the method as his, and blamed those writers who spoke of the forceps of Mariaud (an instrument-maker) and the bed used in ovariotomy, when it and all such instruments were made after M. Péan's designs. He did not claim to have invented the word "forcipressure," which belonged to M. Verneuil, who acknowledged it. (Upon inquiry we have learned that M. Koeberle claims to have invented all the methods of applying pressure by forceps, so that this part of the question is complicated.) At the moment of writing the Congress continues, with a very large attendance.

To turn to our usual work, an interesting clinic on the "Treatment of Simple Chancre and its Complications," by Dr. Mauriac, at the Hôpital du Midi, will serve to show the present mode of treatment in France in these affections, and if it is not original it may at least be useful. This hospital is an ancient and celebrated one for syphilitic diseases. It has three hundred and fifty beds, and it was first of all set aside for the use of nurses and newly-born syphilitic children, but afterwards it admitted all persons having venereal diseases. A few years ago a further change was made, and the sexes were separated by the creation of the Hôpital de Lourcine for women with these disorders, leaving this hospital for males only, so that at present it is one of the most important here for the study of venereal diseases. Professor Fournier's service at the Hôpital St. Louis still continues also to attract the attention that it deserves under the direction of that eminent speaker. Custom in the United States has warranted the name of "chancroid" for what the French call "chancre simple," but they both mean that form of contagious venereal disease or ulcer which is not accompanied by any constitutional syphilitic infection. Dr. Mauriac showed, in his opening remarks, that it was a local virulent affection that seldom extended farther than the nearest lymphatic ganglions. He noted as a curious fact that great accumulations of individuals constitute a cause of increase in this disease. For instance, in 1875, as at present, there was very little of this disease, but in 1878, when the city was so full, owing to the Paris Exhibition, there was a considerable increase, a very large number of cases being treated. So he thinks that the coming Exposition in 1889 will largely increase the number. (Happy prospect!) We pass over the doctor's excellent description of chancroid and its complications, and come to the treatment, as being the part most interesting to compare with ours at home. He said, "In speaking of the diagnosis I have let you see that modern therapeutics is not powerless before this affection and its complications, and I then said that many liquids will destroy chancroid,—such as all the acids, all the alkalies, alcohol, chloroform, and even vinegar,—but I will add a formula the efficacy of which has often been proved to me:

℞ Acid. citric., 3 grms.;
Acid. hydrochloric., 3 grms.;
Tinct. ferri perchloridi, 3 grms.;
Aquæ, 30 grms. M.

This you will apply yourselves as wanted. Destructive cauterization is indicated only when the chancroid is commencing, and when it is not situated on parts which we may fear to attack,—for instance, when it is near the urethral canal, and where one might produce a fistula; also it is contra-indicated when the sore is of great extent. If you decide on caustics, take the most energetic ones (and the best is the chloride of zinc). Diday employed equal parts of wheat flour and chloride of zinc, and he applied it in the form of a ring just the size of the chancroid, which he left in place until it melted: it certainly protects the neighboring epidermis. I, however, use a saturated solution of chloride of zinc, with which I paint the ulcerated surface sometimes twice or three times, but often only once will bring about a modification, and a radical change will show itself first in the disappearance of the pain in the chancroid (which do not confound with the pain produced by the cauterization itself, which is very severe); soon after you will notice that the surface of the ulceration has changed, its borders will fall away, and the centre will rise; but wait still some four or five days before promising a cure, as a small portion of it that has not been attacked by the caustic will be quite sufficient to reinoculate the disease, and your work must be done over again. When there is phagedænism I prefer the use of the thermo-cautery. Chancroid being an acute affection, it has been said that it is useless to cauterize, and some physicians employ frequent washing of the part with aromatic wine or this solution:

℞ Chloralis, 3 grms.;
Aquæ, 300 grms. M.

Iodoform is difficult to employ in city practice, owing to its bad odor: this is a pity, as it will modify it very quickly and take away the pain. All these different substances may be indicated according to the seat of the chancroid. Remember never to cauterize them when they are on or close to the frænum penis or in the vaginal *culs-de-sac*. In women, as a rule, they heal more easily than

in men, and you will not need in their cases such energetic measures. Nitrate of silver is not bad, but employ it always in solution; never use the stick- or pencil-form, as it will wound the lymphatic vessels, which many practitioners think is the starting-point for venereal bubo.

"The treatment of the complications of chancroid merits your best attention: by itself, it is an inflammatory process that may be accentuated according to the patient's temperament or habits (alcoholism, etc.), so that a cauterization badly done may lead to a violent inflammation, and on to gangrene or phagedæna. Often these general causes are aided by a local one, such as paraphimosis, etc. The rule is to open all closed parts and wash them out with a solution of hydrate of chloral or boric acid. Phagedæna is a sort of molecular gangrene which depends not on the malady itself, but on the condition of the patient. Outside of ordinary causes, such as bad air or food, alcoholism, etc., there are individual cases occurring in persons who seem to be in the best of health otherwise. The chancroid takes a pale aspect, the borders get livid, and the ulcerated surface increases on all sides: cases have even been known that extended to the groin and perforated the bladder. It is very difficult to treat: tonics, iron, change of air, good hygiene, etc., are of first importance. Locally, cauterization is the treatment, but unless done at once it must be used with great caution; and here iodoform becomes a most precious remedy, dusted on well three times a day. The powder named after Bellini has been advised, but it is very dear and the formula is not constant. Another complication is the extension to the lymphatic system of the groin. Frequently it will extend only to the nearest lymphatic ganglion, but, as a rule, when your patient complains of pain in the groin, and there is a swelling, he has a bubo, and in a few days it will be ripe in most cases. The bubo most often appears in three or four weeks after the chancroid. As soon as you see it I advise you to make a puncture into it clear down into the gland itself; then you will most likely see some pus come out, which will relieve the tension, but you have not destroyed the virulent nature of the tumor in this way. It will be necessary to attack it with caustics, and, as before, chloride of zinc is the best to use. However, do not commence at once; you must wait for five or six days after the opening of the abscess, otherwise the chloride of zinc might fuse over into the adjoining tissues: so wait until it has well opened, and in the mean time use dressings of chloral solution."

New Method for Detecting Albumen in Urine.—Professor Quinquand, speaking at the Société de Biologie this week, gives this new method to determine the presence of albuminoid substances in urine. It is very simple, and ought to find great use in all clinical practice. It consists in simply filtering the urine and then adding to it a few drops of the well-known copper solution of Barreswill (that is used to detect sugar in urine). It is then heated up, and at once a characteristic and beautiful violet color appears (that is, if there is the slightest trace of albumen in the urine). Dr. Quinquand says that there are a number of kidney-alterations in which the albumen is rarely detected by the means usually employed, but that this solution will show the faintest trace of albumen in urine. We are reminded here that it is generally Fehling's solution that is used in America for sugar, and not that called Barreswill's here (which is the one Dr. Quinquand means), so we add the mode used here:

"*To Make Barreswill's Solution.*—Take 40 parts of crystallized carbonate of sodium, 50 parts of cream of tartar, and 40 parts of caustic potash, and dissolve them in 400 parts of water; also mix (apart) 30 parts of sulphate of copper in 250 parts of water; add these two solutions together and filter them, then add filtered water enough to make a litre in all."

To Purify the Air in Wells.—Several men having been killed here lately by the vitiated air in wells they had descended to make some repairs, M. Gréhant recalls attention to his recommendation always to introduce an animal into such wells before attempting to descend; he also now suggests a plan to draw the impure carbonic and other gases out of them by the use of a section of stovepipe, which is lowered into the well and fastened, and then a fire of charcoal is placed around the pipe at its upper extremity, a short distance from its summit, and at once on its heating up there will be a draught of air from within outward which will soon purify the well; but an animal must be tried on it first always for an hour before allowing men to descend.

Injection of Gaseous Medicaments per Rectum.—We said something in a former letter on this subject, which is now attracting great attention here. Professor Cornil spoke about it at the last meeting of the Académie de Médecine. Claude Bernard first showed that gases injected into the rectum were eliminated by the lungs without provoking any such accidents as the inspiration of the gases might cause. When we mix carbonic acid gas (which is very well tolerated by the rectum and lungs) with some medicated gas or vapor and have it injected per rectum, this last will be eliminated by the pulmonary air-cells, on which it will act directly.

The results obtained by this method which have been reported are most satisfactory: the respiratory rhythm is favorably modified; there is an increase of strength and a disap-

pearance of the fever and night-sweats. It was first tried by Dr. Bergéon, of the Faculty of Lyons, and is at present being used by Dr. Chantmesse, the chief of the pathological laboratory and physician to St. Antoine Hospital in Paris. So far it has been used in cases of asthma, bronchitis, whooping-cough, and pulmonary phthisis. Two of Dr. Chantmesse's patients who had severe attacks of asthma were given at once on entering the hospital injections of carbonic acid gas charged with sulpho-carbonated vapor, and there was an almost immediate relief in the dyspnœa, while after a few days' treatment the respiration became free. Nine other patients in the same service who had phthisis, with presence of the characteristic bacilli in the sputum, also obtained a considerable amelioration; the augmentation in weight was remarkable (from one to three pounds a week), with the cough and expectoration very much diminished. One of the last-mentioned patients gained nine pounds in six weeks. Care must be taken in the use of the different gases,—chlorine, bromine, ammonia, iodine, and turpentine,—some of which will cause inflammation of the intestinal mucous membrane. To use this treatment two operations are needed:

1. Manufacture pure gas, to prevent intestinal intolerance. To do this, take a large wide-mouthed bottle and put in it first of all three tablespoonfuls of bicarbonate of sodium, and adapt to this bottle a rubber cork with a rubber tubing coming from it to allow the gas to pass, and a hole to allow a funnel (glass) to be passed in; then make a solution of dilute sulphuric acid (of two hundred grammes of acid to a litre of water), pour this into the flask from time to time by the funnel, and as the gas escapes receive it in one of the rubber sacks that dentists use for nitrous oxide gas, holding about six litres.

2. The second operation consists in retaking this carbonic acid gas, mixing it with the medicinal vapor, and introducing it into the rectum with the usual form of rubber bulb and tubing; or the carbonic acid gas can be made to pass through a bottle containing the medicament.

Professor Cornil has instituted a series of experiments in his service at the hospital, and he will give the results soon: we will visit the patients also, and be able to give a personal report of the method.

THOMAS LINN, M.D.

PARIS, October 22, 1886.

NEW YORK.

THE cause of medicine is not asleep in this city. The medical societies, including the Academy of Medicine with its several Sections, the Medical Society of the County of New York, and the Pathological Society, have begun work actively, and, if we may judge from the amount of material presented at the first two or three meetings of what will come during the remainder of the season, there will be no complaint on the part of the medical journals for want of matter with which to fill their pages. Abstracts of the scientific proceedings of several of the Societies have already appeared in the *Times*, but mention may here be made of a donation to the Academy of Medicine of twenty-five thousand dollars by Mrs. Woerishoffer, who was induced to make the donation because of the interest manifested by her husband in the advancement of medical science, and because of the high and purely scientific position taken by the Academy, and its growing need for more room and for a fire-proof building to receive its large library. Ex-President Dr. Fordyce Barker, in offering resolutions of thanks to Mrs. Woerishoffer, expressed the hope that the Academy would soon come into possession, through the liberality of the wealthy people of the city, of a million dollars, the amount which he had formerly said was needed to make it the centre of medical science in this city, as it was destined to be.

Philadelphia people who are in a position to be charitable have come to recognize the wants of medical science and art, as has been repeatedly shown of late by donations of large sums for building hospitals and institutions for advancing medical learning. Henry George says, "All honor to the Astors and the Coopers for their gifts of libraries to the people, but," he adds, "it is no honor to the people to have to accept such gifts, for they should be in a position to build institutions for themselves." The doctors seem to think that, until they shall arrive at a point where they can build institutions worth a million dollars for themselves, they will give honor to those outside the profession who are able and willing to found such institutions for them.

While on the subject of donations to medical institutions, let me say that the new building for the College of Physicians and Surgeons will be completed and in use a year from now. The walls are up, and one can get a good idea of how the building will look when completed. The main entrance faces Fifty-Ninth Street and Roosevelt Hospital; joining the two wings, one facing Fifty-Ninth Street and the other Sixtieth Street, is the building containing the large lecture-room or amphitheatre. The structure is principally of a light-red brick. Not being wedged in between other houses, there will be a better opportunity for architectural effect than is possessed by some of our medical institutions.

It is understood that the medical department of the University of the City of New York will commence erecting the laboratory, for which a donation of one hundred thousand dollars has been received, next spring.

Bellevue has new and comfortable seats in

its amphitheatre, together with a place under the seat to put one's hat. The arms are high, making it somewhat inconvenient for taking notes during the lecture. It is a noticeable fact that our medical colleges have not a free coat-room: hence the unseemly stacks of wearing-apparel in the lecture-room.

Our medical colleges start out with even more than their usual number of students. At the College of Physicians and Surgeons about seventy more are enrolled than at this time last year, and at the University about fifty more, while Bellevue has its quota. One of the requirements for graduation at Bellevue is a course in the Carnegie or some other pathological laboratory, including the study of pathological and histological anatomy and the examination of the urine. At this college Dr. Janeway fills the position made vacant by the death of Dr. Austin Flint. At the University, Surgeon Billings, U.S.A., lectures on hygiene in October; the Chair on Physiology in this college having been left vacant, lectures in that branch will be delivered by Dr. W. C. Thompson and Dr. E. J. Bartlett; Dr. W. M. Carpenter has also been put down for a medical clinic in January; Professor R. A. Witthaus fills the Chair on Chemistry.

At the College of Physicians and Surgeons Dr. George L. Peabody fills the place of Professor Edward Curtis on Materia Medica, Professor Tuttle lectures on Gynæcology, and the names of Dr. W. T. Bull and Dr. R. A. Hall appear, in connection with those of Professors Markoe, Sands, and Weir, in the department of surgery.

At the meeting of the Medical Society of the County of New York, October 25, Dr. Laurence Johnson was elected President and Dr. F. R. S. Drake Vice-President. At this meeting Dr. Drake, of the Board of Censors, read a report from Mr. Purroy, counsel for the Society, regarding the prosecution of illegal practitioners, by which it appeared that out of over three hundred cases investigated during the year proceedings were instituted in forty-four, and, excluding some in which the clemency of the Society was shown, and a few others in which a trial had not yet been reached, all had been convicted. It may be remarked that the Society is doing a good work in freeing the community of a dangerous class of so-called medical men, and in a manner not to indicate, nor to appear to indicate, undue severity or self-interest. The Society has been very lenient wherever there has been any just warrant for leniency.

As bearing upon medical ethics, the question of recommending proprietary medicines arose, and a fact was brought out by some remarks made by Dr. Drake which merits the attention of the profession. On a circular recommending a proprietary medicine Dr. Drake's name, and that of Dr. Loomis, appeared without their previous knowledge. They wrote, calling the owner's attention to it, and were favored by an impertinent reply. They then threatened suit, but a compromise was reached. Probably many of the numerous recommendations of proprietary articles by physicians appear without the presumable author's knowledge, and if some one would bring suit and obtain exemplary damages it would probably put a stop to such piracy. We see appended to a recommendation of some nostrum the name of Secretary Manning, Dr. Davis, or some other distinguished person, and, while we know that it is not at all probable that either of these gentlemen would give such a recommendation even if he had experimented with the nostrum, yet the proprietor knows also that it is not likely that Mr. Manning or the other gentlemen will ever see the advertisement, and that they will not be likely to have either time or disposition to reply to letters inquiring whether they had written such a recommendation. Moreover, not all the people who read it would write to those distinguished gentlemen, asking whether it were true. Thus the quack without conscience is sure to reap a harvest by the lie, while the people are the asses who give him the harvest,—viz., their money. I would suggest, however, that, although the people are so willing to play the part of asses, it is no reason why the impostors should not be made to feel the weight of the penal law.

The Institute for carrying out Pasteur's method of inoculation against rabies, under the charge of Dr. Mott at the Carnegie Laboratory, has had little material to work upon. It would seem that but few persons in this country are bitten by mad dogs, or else that those who are bitten have too little faith in the method to submit to the inoculations. It would also seem that there is an impression in the minds of the people that the method may prove not altogether harmless; otherwise, if they thought it offered even but the slightest chance of preventing the development of so terrible a disease, it would become fashionable to go to the Institute when bitten by a dog, whether it were mad or not.

The post-graduate medical schools are prospering. The Secretary of one of the schools told me that they had on their list two ex-presidents of a State Medical Society and several professors in medical colleges. Their class, he said, is larger by a very considerable number than that of any previous year. Being asked whether they met with any opposition from the colleges which confer the degree of Doctor in Medicine, he replied, "Not in the least;" that they were on the best of terms. As they received only graduates in medicine, the only effect their attendance had upon the medical colleges was to diminish the number of matriculants at those colleges, not diminishing the number of their graduates.

R. C. S.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

AT a stated meeting of the Academy, October 21, 1886, the President, A. JACOBI, M.D., in the chair, a gift to the Academy of twenty-five thousand dollars from Mrs. Woerishoffer was accepted, and her name and that of her husband ordered placed on the roll of permanent benefactors.

The death of Ex-President Dr. Anderson, at the age of eighty-seven years, was announced by the Statistic Secretary.

PULMONARY EMPHYSEMA.

Dr. FRANCIS DELAFIELD read a paper on this subject, illustrated by the stereopticon. He first gave a general idea of emphysema obtained from the text-books, and said that while they were such as the student entertained at the time of graduation in medicine, he soon found that those ideas did not correspond with what he observed. He found that compensating and senile emphysema were not of much importance, but that substantive emphysema was, and that it was a very common and a very serious disease. He found at the autopsy that dilatation of the air-vesicles was not always in proportion to the severity of the symptoms. If he injected the blood-vessels of the lungs artificially he found that he could obtain a very perfect injection, and he could not see exactly where the alleged obliteration of the capillaries could be. He noticed that very few patients had blown on wind-instruments, that many had not had bronchitis, and he doubted whether the expiration and inspiration theories were of much value. He found that many cases were hereditary; that the immunity from phthisis and pneumonia in patients with emphysema was hardly all that could be desired; that the barrel-shaped chest was not so often present as he had expected; that exaggerated vesicular tympanitic resonance was not very common. He was occasionally puzzled by cases which seemed to be cases of emphysema, but which had not the symptoms which he had been led to believe were characteristic of that disease. It seemed, therefore, worth while to abandon the traditional symptoms of emphysema, and to state fairly what we do and what we do not know about the disease.

If we considered all the cases of vesicular emphysema, they could be divided into three classes, as heretofore,—namely, senile, compensating, and substantive emphysema. Senile emphysema was of common occurrence, although not of great importance. It seemed to be a senile change in the parenchyma of the lungs. The walls of the vesicles were thin; their cavities dilated; they might rupture into one another. There was, however, no obstruction to the passage of the blood through the lung, no dilatation of the right ventricle of the heart, no general venous congestion. This condition, when well developed, gave the loud vesicular tympanitic percussion-note said to be characteristic of emphysema. There was no marked dyspnœa, but chronic bronchitis was often present. The disease had no decided effect on the general health. He believed that in some patients substantive emphysema was first developed, and as they grew older it was modified by senile changes into something resembling senile emphysema. It was not always easy during the life of the patient to distinguish between senile and substantive emphysema, especially as chronic bronchitis might be present with both. But a distinction was important, as substantive emphysema was a serious matter, while senile emphysema was not.

Compensating emphysema involved only one lung or a part of one lung. It was seen most frequently with phthisis and with compression of the lung following pleurisy. In some cases the change in the lung seemed to be simply hypertrophy of its tissue, while in others there was a dilatation of the air-vesicles and a thinning of their walls. In still others the emphysema, although it might seem to compensate for the obstruction or obliteration of lung-tissue, was like substantive emphysema.

Substantive emphysema was formed by chronic inflammation, a pneumonia; and dilatation of the air-vesicles was more the result of this inflammation, and not the essential lesion of the disease. The inflammation was of the same type as that which so often attacked the endocardium, the inner coat of the arteries, the liver, and the kidneys, a chronic inflammatory change with the production of new fibrous tissue, and at the same time with atrophy and disappearance of normal tissue. The walls of the air-vesicles and of the air-passages were the parts of the lungs first involved in inflammation. These walls were in some parts of the lungs thickened, and in others thinned. Where the walls were thinned there was apt to be dilatation. Such a dilatation affected the air-passages rather than the air-vesicles, and might be confined to the former. The degree of dilatation varied very much in the different cases. It was not in relation to the severity of the symptoms, and the disease might go on to its fatal termination with hardly any such dilatation. He did not mean, however, that the condition of the lungs was not made worse by the dilatation. It unquestionably was; but, on the other hand, most of the symptoms of emphysema might be present, and the disease prove fatal with but very little dilatation. In fact, he believed that many cases of emphysema were overlooked at autopsies because no dilatation of the air-spaces was visible to the naked eye. In some cases there were little

holes in the walls of the air-passages and vesicles, formed in the spaces enclosed by capillary blood-vessels. They were found both at the periphery and at the centre of the vesicular walls, usually several in a single vesicle, some very minute, others of considerable size. Their edges were sharp-cut. They were found in vesicles of normal size as well as in those which were dilated. Although these changes in the air-vesicles constituted the essential lesion of substantive emphysema, yet the emphysema extended, as a rule, and reached other parts of the lung; and the epithelial cells which lined the air-spaces were increased in size. The mucous membrane of the bronchi became the seat of catarrhal inflammation. The disposition to the formation of new connective tissue became more marked, so that the walls of the air-cells were very much thickened and their cavities deformed and obliterated. The septa between the lobules, the walls of the bronchi and blood-vessels, and pulmonary pleura were all thickened, and very frequently there were also extensive pleuritic adhesions, so that the entire lesion assumed the form of a well-marked interstitial pneumonia.

In the milder cases there was no disturbance of the circulation of the blood, but in the severer cases such disturbances of the circulation became one of the worst features of the disease. It seemed evidently to be due to some obstruction to the passage of the blood through the lungs, for the right ventricular wall became dilated and hypertrophied, and venous congestion of the viscera and of the skin, and dropsy, were established. It had been said that the obstruction to the passage of the blood through the lungs was due to dilatation of the air-spaces and the obliteration of the capillaries in the walls. This explanation certainly could not be true for all the cases, for he found the most marked evidences of general congestion in cases in which dilatation of the air-spaces was trifling, and the complete artificial injection of the blood-vessels could be easily made after death. He believed that in a large number of cases the obstruction to the passage of the blood through the lungs was due not to structural changes, but to contraction of the small arteries in the lungs which existed during life and disappeared after death.

Dr. Delafield then gave the secondary lesions of emphysema. It was apt to begin between the ages of forty and forty-five years. Hereditary influence was marked. In general he could say that the same causes which led to chronic endocarditis, chronic endarteritis, cirrhosis of the liver, and chronic diffuse nephritis, also led to the development of substantive emphysema. Clinically it was much more important to observe the cases in which the disease was but moderately developed than those in which it was advanced, for moderate cases were to be benefited by treatment, while bad ones comparatively were not. In the lesser degrees of emphysema there was no change in the shape of the thorax; in the more advanced cases there was prominence of the sternum and of the costal cartilages. In very bad cases the barrel-shaped deformity might be reached. Pulmonary resonance might remain unaltered for a considerable length of time. When changed, it was either a rather dull note of wooden quality or exaggerated resonance, of vesicular or vesiculo-tympanitic quality. The respiratory murmur was feeble, or there was feeble inspiration with longer, louder, low-pitched expiration, or both inspiration and expiration might be exaggerated, loud, and high-pitched. Bronchitis, when present, added its sibilant and sonorous breathing and râles.

There were many persons in whom substantive emphysema developed and continued for years without giving rise to any rational symptoms, and yet even in such persons it was often possible to be pretty sure of the presence of the disease, because they were persons whose general physical condition and age were such as were usually associated with emphysema. There were other patients in whom associated Bright's disease or cardiac disease gave rise to symptoms so marked that the emphysema passed unnoticed. In the regular cases dyspnœa was one of the most marked symptoms, at first developed only by exertion, and later existing perhaps constantly. It was a question of importance as to how much the dyspnœa was due to the condition of the lung-tissue and how much to the contraction of the blood-vessels. The complicating bronchitis gave rise to a variety of symptoms,—cough, expectoration, hæmoptysis, febrile movement, night-sweats. General venous congestion gradually developed. Having described the course of the disease in different patients, Dr. Delafield said its behavior was very much like that of atrophic chronic Bright's disease,—a slow inflammation, which gradually changed the structure of the affected organs. The organs, however, continued to perform their functions moderately well until their structure had become changed a good deal, and, in addition, disturbance of the circulation had been established. Then, either gradually or with a sort of explosion, the decided symptoms of the disease made their appearance.

The views which he wished to urge on his hearers' attention were: First, that substantive emphysema was not a local chronic disease due to rarefaction of the pulmonary structure and dilatation of the air-sacs, but a chronic inflammation of the lung. It was not due to excess of inspired air over expired air. Nor was the dilatation of the air-spaces the essential part of the lesion. The result of the inflammation was such an irregular

thickening and thinning of the walls of the air-spaces as would naturally be followed by dilatation. That excessive bodily exertion might render the dilatation greater than it otherwise would be seemed probable, just as in aneurism of the aorta we must have first disease of the wall of the vessel, and then excessive muscular exertion, to produce dilatation. That the dyspnœa and general congestion were not due simply to the dilatation of the air-spaces nor to the obliteration of the capillaries, but rather to the contraction of the blood-vessels. That the main indications for treatment were to delay the progress of the chronic inflammation and to overcome the contraction of the blood-vessels.

Dr. E. DARWIN HUDSON thought the view taken of pulmonary emphysema by the author of the paper was essentially a pathological one, whereas he had studied it chiefly from the stand-point of physical diagnosis and treatment. He was still of opinion that emphysema (in its typical form) was essentially, as defined by many of the old writers, a rarefaction of the terminal bronchi and walls of the air-cells, with dilatation. He thought one of the several pneumatic cabinets would be beneficial in treatment.

Dr. CHARLES HEITZMAN said his pathological studies supported the view taken by Dr. Hudson. He thought the cases described by Dr. Delafield were not cases of pure substantive emphysema, but combinations of emphysema with chronic interstitial pneumonia. He had many specimens illustrating the disease in its simple form.

Dr. R. VAN SANTVOORD had employed caffeine with benefit, and he thought it acted in the way Dr. Delafield had suggested, by relaxing the contracted small pulmonary vessels.

The PRESIDENT thought iodide of potassium, by producing absorption of the inflammatory products, would be beneficial.

Dr. DELAFIELD had found caffeine and convallaria specially stimulating to the right side of the heart, and of benefit in emphysema, as well as in other conditions requiring stimulation of the right auricle. As to iodide of potassium, it was useful because, as he thought, of its relaxing action upon the blood-vessels.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 13, 1886, the President, JOHN A. WYETH, M.D., in the chair.

Dr. H. MARION SIMS presented, in behalf of a candidate, specimens illustrating carcinoma of both ovaries, and of the colon and liver, together with a small fibro-myoma in the walls of the uterus, and suppurative inflammation of the kidneys.

The PRESIDENT presented, for a candidate, a specimen of cysto-sarcoma of the mamma.

CHRONIC DIFFUSE NEPHRITIS.

Dr. CARPENTER presented, for Dr. H. J. BOLDT, the kidneys of a man who died rather suddenly, aged 45 years. He had recently begun to drink heavily, but was in comfortable health and conscious to within fifteen minutes of death. He had had no symptoms of uræmia. The kidneys presented the lesions of chronic diffuse nephritis; the heart was hypertrophied; the brain and other organs were normal.

PECULIAR BROMIDE ERUPTIONS ON THE LEGS.

Dr. R. W. AMIDON presented a young woman, subject to epilepsy, who for about four years had been under his treatment, taking moderate doses of bromide of potassium, perhaps never more than four or five drachms a day. Over a year ago she discontinued it, but recently he learned that she had been taking during the past eighteen months a mixture of the bromides amounting to six drachms a day. She then returned to Dr. Amidon, and he found the ordinary acne eruption on the face, but this usually was confined to the face and neck, perhaps occasionally reaching the chest and shoulders. But in this patient, and in two others whom he had seen, the lesion had invaded the legs and assumed almost the pustular form. He had found a description of the lesion in only one book. It commenced as a large single acne eruption, which became inflamed, with indurated, rather large base, and after rather a chronic inflammation broke down, forming what appeared to be a small ulcer: vesicles which tended to become cloudy and purulent formed in rings about the acne-spot. After a time the centre of the spot took on a reparative process and entirely healed, while the pathological changes at the periphery spread, and the vesicles became purulent, dried up, and formed a brownish scab. A section of one of these spots showed that there had not been a true ulcer; that the skin had simply been denuded of the cuticle, leaving the papillæ intact. He had in no case seen the true skin entirely invaded. The disease ran a slow course: it did not seem to depend particularly upon the amount of the bromides given. The only treatment which he had seen do good was the thorough application of the actual cautery. Dr. Amidon showed photographs of the other cases.

SIMPLE *versus* MALIGNANT ACUTE ULCERATIVE ENDOCARDITIS.

Dr. T. MITCHELL PRUDDEN presented four hearts and some culture-specimens of the Staphylococcus pyogenes aureus. In the first three cases the patients had died with the symptoms of acute ulcerative endocarditis, and the post-mortem examination confirmed the diagnosis of simple acute ulcerative endocarditis, with absence of bacteria in the diseased tissue on the endocardium. In the

fourth case, that of a girl who had developed pyæmia following a surgical operation, attended by the symptoms of acute ulcerative endocarditis, the Staphylococcus pyogenes aureus was demonstrated by the culture-method, placing the case among the malignant or bacterial variety. Inoculations of the bacteria into rabbits, with and without wounding the endocardium, were made, and in those with injury acute malignant ulcerative endocarditis developed, while in the others no endocarditis developed. Lesion of the endocardium without injection of the bacteria was also unattended by the development of the disease. These experiments went to show that a previous lesion or predisposing condition had to be present in order to invite the bacterial endocarditis. In the case of the girl, the malignant endocarditis developed on a chronic endocardial lesion.

Dr. Prudden said the cases emphasized the distinction between malignant and simple acute ulcerative endocarditis,—in the one case the bacteria being present, in the other absent.

MITRAL STENOSIS—THROMBOSIS OF THE RIGHT AURICLE.

Dr. R. VAN SANTVOORD presented the heart of a boy, aged 10 years, in whom the diagnosis of acute ulcerative endocarditis was made, whereas the autopsy showed only mitral stenosis and a thrombus in the right auricle. There had been petechial spots over the body, and general œdema, and a double mitral murmur was present.

ULCER OF THE COLON—ABSCESS OF THE LIVER.

The specimens were presented by Dr. FRANK FERGUSON, with a brief history. Dr. Ferguson also presented the brain illustrating

ANEURISM OF THE POSTERIOR BRANCH OF THE MIDDLE CEREBRAL ARTERY.

The patient, aged 48 years, died about four hours after falling suddenly and becoming unconscious. He had previously been healthy.

MALARIAL PIGMENTATION.

Dr. FERGUSON also presented specimens from two patients who had died after having suffered from malarial fever. Pigment was present during life in the blood, and at the autopsy all the organs of the body, especially the brain and the stomach, were exceedingly dark from pigmentation.

LARGE CYSTIC TUMOR OF THE SCALP.

Dr. ROBERT NEWMAN presented a cyst, about the size of an orange, removed entire from the side of a woman's head.

NASAL POLYPUS.

Dr. FERGUSON also presented the remains of a large nasal polypus, the last part having been removed by Jarvis's snare, it being the only case in which he had found the snare superior to the galvano-cautery and torsion.

REVIEWS AND BOOK NOTICES.

THE MATHEMATICAL THEORY OF ELECTRICITY AND MAGNETISM. By H. W. WATSON, D.Sc., F.R.S., and S. H. BURBURY, M.A. Vol. I. ELECTROSTATICS. Large 8vo, pp. xii., 268. New York, Macmillan & Co., 112 Fourth Avenue.

For a work of this magnitude and excellence the authors are certainly modest, in their preface, as to their claim for originality. That the treatise will compare very favorably with Maxwell's great work, or Gordon's, is evident at a glance. Whilst the greater part of this volume is strictly mathematical in its deductions, it is not at all abstruse or too difficult to follow in the hands of any student ordinarily proficient in algebra. The theory involved is that of two fluids, and the treatment is well handled. The chapters on Potential, on Theoretical Inversion in Electrical Problems, Electrical Systems in Two Dimensions, and Electrical Energy are specially instructive, and the book as a whole is indispensable to investigators in every branch of electrical work or research. W. R. D. B.

TABLETS OF ANATOMY. By THOMAS COOKE, F.R.C.S. Eng., etc. Fourth Edition, or Selections of the Tablets believed to be Most Useful to Students generally. London, Longmans, Green & Co., 1885. Small quarto, pp. 294.

These tablets have for their origin a synopsis of demonstrations given by the author in the Westminster Hospital Medical School some years since. They are convenient for students who are preparing for examinations, and form a useful companion to the several dissector's manuals in impressing dry anatomical details upon the mind: they are intended especially for those who, having already gone over the subjects treated of, desire to review the main points rapidly and comprehensively. For such the present publication offers special advantages.

CUTANEOUS MEMORANDA. By HENRY G. PIFFARD, A.M., M.D. Third Edition. New York, William Wood & Co., 1885. 24mo, pp. 268. (WOOD'S POCKET MANUALS.)

This illustrated manual in twenty-four chapters considers the anatomy and physiology, the pathology and therapeutics, of the usual disorders of the skin. It is clearly written, and the directions for treatment are intelligible. On account of its terseness and directness of statement, the work is of great service to students.

NEW REMEDIES AND CLINICAL NOTES.

THE PHYSIOLOGICAL TREATMENT OF CHOLERA, AFTER SEMMOLA.—We abstract from a recently-published work, "Nuove Ricerche terapeutiche sul Cholera Asiatica," in which this well-known Italian clinician has laid down the clinical and therapeutic experiences gathered during the recent Italian epidemic of cholera, his views on what the author calls the "physiological treatment of cholera." Semmola holds that no cure can ever be expected from any medication directed specifically against the comma-bacillus, and also warns of too heroic a therapeutic interference with the symptoms of the premonitory and algid stages.

A physiological treatment, in the judgment of the author, is one which is directed towards raising the vital energy of the body, so as to endow the same with a higher power of resistance against the disease without injuring the entire system by the bio-chemical action of pharmacal agents.

The main features of this treatment are the following:

1. Absolute rest of the affected organs—viz., the gastro-intestinal tract—by observing a strict fasting on appearance of the first diarrhœa stools. As long as the diarrhœa persists, no food whatever is to be taken. Over six thousand clinical observations in Naples have shown that even five or six teaspoonfuls of bouillon given prematurely (*i.e.*, before the stoppage of the diarrhœa) sufficed to reproduce the gravest symptoms, such as algidism and asphyxia. After the disappearance of diarrhœa and vomiting, milk may be given in very small quantities.

2. Timely excitation of the physiological powers by therapeutic, or, rather, by physiological, means. The best of these are undoubtedly repeated warm baths. To prove beneficial the baths must, however, be given in the first period of the disease, before any sign of algidism has set in. The application of the warm bath in cholera has been in vogue also in former times, but never yielded any benefits, as it was employed only in the algid stage of the affection. The warm bath is not alone useful, as was held formerly, on account of the supply of heat to the cold surface of the body (a mere physical process), but also and particularly on account of the physiological influence it exerts on the economy. The warm bath excites the peripheral nervous system, and at the same time, by reflex action, the centre of circulation. The consequence of this excitation is a harmonious restoration of the functional physiological relations between the surface of the body and its internal apparatus, especially those of the digestive tract. True, this biological process can be realized only in the first stage of the disease, when the biological relations between the superficial and internal organs have not yet been essentially altered or broken off altogether.

Through diaphoresis the bath favors besides the elimination of toxic substances from the system, which, by affecting the various nerve-centres, cause ominous alterations in the secretory, vaso-motoric, and general oxidation processes. If necessary, the bath can be repeated every one or two hours. After the bath the patient is to be wrapped up in woollen blankets, and is to be given warm aromatic and weak alcoholic drinks. It is well to give also small doses of opium (laudanum, liqueur de Battley, chlorodyne), in order to render the nervous centres less susceptible to the toxic principles, and in order to reduce the increased intestinal secretion. Opium, given at the proper time, aids and supplements the physiological treatment. —*Therapeutic Gazette*, October 15, 1886.

COCAINE IN WHOOPING-COUGH.—Dr. L. Emmett Holt (*New York Medical Journal*) tried cocaine in five cases in young children, with the result of developing serious nervous phenomena. He concludes his paper, which was read before the New York Clinical Society (September 24), with the following practical deductions:

"1. Cocaine must be used with great caution in young children under all circumstances.

"2. The spray is never to be recommended, since an uncertain quantity is given.

"3. Solutions stronger than four per cent. should not be used by swab or pencil in children under two years, and in older ones only with great caution. This remark applies to the rectum as well as to the throat.

"4. In the cases where it was tried he failed to see any notable benefit in the disease.

"5. Chloral seemed to be of very decided value in controlling symptoms due to cocaine." He suggested a more extended trial of it in this direction.

GELOSINE AS A VEHICLE FOR EXTERNAL MEDICATION. — Gelosine is a mucilaginous principle extracted from the *Gelidinum corneum*, a native of Japan. It is a colorless, amorphous, non-nitrogenous substance which forms the basis of vegetable jellies. It is soluble in warm water, rendering solid on cooling five hundred and fifty times its own volume, the result being a fine transparent jelly, which is very slow to undergo putrefactive changes. M. Guérin considers that gelosine is admirably adapted for purposes such as poultices, vaginal and urethral suppositories, etc. The jelly undergoes gradual contraction, in which process any medicinal substance contained is slowly expressed until complete desiccation is effected, thus bringing it constantly into contact with the skin. The only preparation needed is to dissolve gelo-

sine in suitable quantity in warm water, and then add the medicinal agent, either in solution or in a state of fine division.—*London Medical Record.*

MISCELLANY.

THE LEGAL STATUS OF A DEAF-MUTE.—The New Jersey Court of Chancery has had before it the question of the capacity of a deaf-mute to manage her property. The case is an interesting one, and the testimony as to the mental condition of the deaf-mute was as follows. "She is about sixty-five years old, and has never been married. The commissioners have made a report concerning her condition. They say that she is not an idiot or lunatic in the popular sense of the words; that she has been a deaf-mute ever since she was two or three years old; that she is ignorant, having never been taught any language, whether spoken or of signs; that she can neither read nor write, and cannot express to others her understanding, if any she have, of any business transaction; that she cannot be made to comprehend a business transaction, except, perhaps, a very ordinary one, involving no more money than a dollar or two; that she has learned to fetch and carry and to do common every-day housework,—that is, she can sweep, wash, cook an ordinary meal, etc.; that it is possible by rude gestures to communicate to her a desire that she should do such work; that she has never managed her property, nor any part thereof, and that the acting trustee of her estate has never informed her of the amount, character, or income of her property, and that it is doubtful whether she can be so informed; that she has always been cared for by her near relatives, with whom she has lived, by her mother for about fifty years and until her mother's death; after her mother's death by her unmarried sister so long as that sister lived, and since that sister's death by her married sister, with whom she now lives."

There were twenty-four jurors called to decide on the inquisition into her case, and of these twenty-four nineteen found that the deaf-mute was of "sound mind and capable of controlling her property by her own selection of a proper person to act for her." The other five certified that she was "not of sufficient understanding to enable her to manage her property." An application was made to the court to set aside the finding of the majority of the commissioners, and this, it would seem, was very properly granted by the court, which held that she could not manage her estate.

The judge said, "If the proof was as the commissioners certify, that she is incapable of understanding the business, or even of receiving any communication upon the subject, and therefore does not understand, and cannot be made to understand, what the necessities of the management of her estate demand, or what an agent is, or what his duties are, or, in other words, if the proof was, as they certify, that she does not understand, and cannot be made to understand, any matters of business, except it may be such as are of the simplest character; if she has no comprehension of business matters, it is obvious that she is not capable of managing her affairs, and the inquisition cannot be sustained. The jury does not find that she is herself competent to manage her business, but that she is capable of controlling it by an agent of her own selection.

"But if she cannot be made to understand what the business is, how can she select an agent to manage it? The inquisition will be set aside."

ELEVATED RAILROADS LIABLE FOR INJURIES CAUSED THROUGH NEGLIGENCE.—A recent case in the Supreme Court of New York is of considerable interest, because the class of accidents it mentions are becoming frequent. The plaintiff was walking along Third Avenue, New York City, and was injured by a hot cinder falling in her eye from the engine of a train on the Manhattan Elevated Railway. On the trial of the action, which was brought to recover damages for the injury, the fact of the accident and the place and occasion were proved, but no further evidence of the negligence of the railroad company was furnished. Upon these facts the trial judge dismissed the case, holding that, as the railroad had been authorized by law, the plaintiff, to recover, must show that it was conducted without the proper safeguards to prevent injury.

The court, on appeal, held that this was not the correct principle, and in an interesting opinion decided as follows: "It would seem to be an extraordinary proposition that a person using as a matter of right the highway, and receiving such an injury as the plaintiff did, should be obliged to show in the first instance that it resulted not only from the defendants' act, but, in addition thereto, that the defendants had not adopted the best means of preventing such an occurrence. This would necessarily involve an examination of the defendants' engine, and an examination scientific in its character, as to whether by any known contrivance it could have been avoided. It would seem more in accord with the principles of natural justice to exact such evidence in response from the company. . . . When the plaintiff proved the injury under the circumstances disclosed, the negligence of the plaintiff was established *prima facie*, and the onus was thrown upon the defendants to show absence of negligence, if it could be done. The injured person cannot be expected to attempt the useless feat of pursuing the train in order to secure an examination of

its locomotive, with a view of discovering what mode was adopted to prevent injuries such as described."

NEW APPOINTMENTS IN THE UNIVERSITY OF PENNSYLVANIA.—Daniel G. Brinton, A.M., M.D., the well-known editor of the *Medical and Surgical Reporter* of this city, and the author of valuable works upon aboriginal American languages, has been elected Professor of American Archæology and Linguistics in the Literary Department of the University of Pennsylvania. The trustees at the same meeting appointed Dr. Morris Jastrow, Lecturer on Arabic and Assyrian; Dr. Herman V. Hillbrecht, Lecturer on Egyptology; Dr. James M. Cattell, Lecturer on Psycho-Physics; and Mr. E. Kelly, Assistant Instructor in Mammalian Anatomy in the Biological Department. Drs. H. Y. Evans, Richard A. Cleemann, and F. S. Stryker were elected Managers of the University Hospital.

HORSFORD'S ACID PHOSPHATE.—We are informed that Dr. W. S. Leonard, of Hinsdale, New Hampshire, has used Horsford's Acid Phosphate in his practice for the past eight or ten years, and has been much gratified with the results obtained from its use. In various forms of dyspepsia it reaches a class of cases that no other medicine seems to touch, and he has repeatedly seen patients, where opiates were contra-indicated, obtain refreshing sleep and rest at night from a single dose at bedtime.

DR. J. R. F. BELL has removed to No. 2028 North Broad Street.

DR. F. B. HAZEL has removed to 841 North Broad Street.

DR. CHARLES S. TURNBULL has removed his office and residence to 1719 Chestnut Street.

NOTES AND QUERIES.

COCAINE-ADDICTION.

MR. EDITOR,—If any reader of your journal has met with a case of cocaine-addiction and will send me the fullest details at his command, I will thank him for the courtesy, reimburse him for any expense incurred, and give him full credit in a coming paper. J. B. MATTISON, M.D.
314 STATE STREET, BROOKLYN.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM OCTOBER 24, 1886, *TO NOVEMBER* 6, 1886.

MAJOR B. A. CLEMENTS, SURGEON.—Died November 1, 1886, at Fort Leavenworth, Kansas.

MAJOR J. S. BILLINGS, SURGEON.—Granted leave of absence for eight days. S. O. 246, A. G. O., October 22, 1886.

MAJOR J. V. D. MIDDLETON, SURGEON.—Ordered from Department of Missouri to David's Island, New York Harbor.

MAJOR A. A. WOODHULL, SURGEON.—Ordered from David's Island, New York Harbor, to Department of Missouri.

MAJOR J. W. WILLIAMS, SURGEON.—Ordered from Department of Colorado to Department of the East.

CAPTAIN J. K. CORSON, ASSISTANT-SURGEON.—Ordered from Jefferson Barracks, Missouri, to Department of Colorado, upon expiration of present leave of absence.

CAPTAIN H. S. TURRILL, ASSISTANT-SURGEON.—Ordered from Department of the Platte to Department of Colorado.

FIRST-LIEUTENANT BENJAMIN MUNDAY, ASSISTANT-SURGEON.—Ordered from Department of Colorado to Jefferson Barracks, Missouri.
S. O. 252, A. G. O., October 29, 1886.

CAPTAIN JOHN V. LAUDERDALE, ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 249, A. G. O., October 26, 1886.

CAPTAIN JOS. K. CORSON, ASSISTANT-SURGEON.—Granted leave of absence for one month, to take effect when his services can be spared. S. O. 246, A. G. O., October 22, 1886.

CAPTAIN E. B. MOSELEY, ASSISTANT-SURGEON.—Relieved from duty in Department of the Columbia, and ordered to report in person at Headquarters, Division of the Pacific, for assignment to duty. S. O. 87, Division of the Pacific, October 16, 1886.

FIRST-LIEUTENANT WILLIAM O. OWEN, ASSISTANT-SURGEON.—Relieved from duty at Fort Schuyler, New York Harbor, and ordered for duty as post-surgeon, Plattsburg Barracks, New York. S. O. 170, Division of the Atlantic, October 29, 1886.

FIRST-LIEUTENANT GUY L. EDIE, ASSISTANT-SURGEON.—Ordered from Fort McIntosh, Texas, to Post of San Antonio, Texas. S. O. 152, Department of Texas, October 27, 1886.

FIRST-LIEUTENANT H. S. T. HARRIS, ASSISTANT-SURGEON.—Ordered from Post of San Antonio, Texas, to Fort Clark, Texas. S. O. 152, Department of Texas, October 27, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FOR THE WEEK ENDED NOVEMBER 6, 1886.

SURGEON J. L. NEILSON.—Ordered to the Receiving-Ship "New Hampshire."

SURGEON M. C. DRENNAN.—Detached from Receiving-Ship "New Hampshire," and granted one year's leave.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED NOVEMBER 6, 1886.

AMES, R. P. M., PASSED ASSISTANT-SURGEON.—Relieved from duty at Marine Hospital, New York, to assume charge of Marine Hospital, Vineyard Haven, Massachusetts, November 1, 1886.

URQUHART, F. M., PASSED ASSISTANT-SURGEON.—To proceed to Norfolk, Virginia, for duty, November 4, 1886.

YEMANS, H. W., PASSED ASSISTANT-SURGEON.—Relieved from duty at Marine Hospital, San Francisco, California, to assume charge of the service at Galveston, Texas, November 1, 1886.

WASDIN, EUGENE, PASSED ASSISTANT-SURGEON.—When relieved, to proceed to New York for duty at Marine Hospital, November 1, 1886.

WILLIAMS, L. L., ASSISTANT-SURGEON.—Relieved from duty at Wilmington, North Carolina, to proceed to Pittsburg, Pennsylvania, for temporary duty, November 5, 1886.

PERRY, T. B., ASSISTANT-SURGEON.—Relieved from duty at Marine Hospital, St. Louis, Missouri, to proceed to San Francisco, California, for duty at Marine Hospital, November 1, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON GONORRHŒAL INFECTION.

Delivered at the Hôpital de la Pitié, Paris,

BY PROFESSOR JACCOUD,

Paris Faculty of Medicine.

(Translated for the MEDICAL TIMES from advance sheets.)

GENTLEMEN,—We will study to-day the patient who lies in No. 37 bed of our "Jenner" ward. He is 37 years of age, a clerk by occupation, and came in on the 12th instant. His history may seem to you to be all dates; but they permit us to come to conclusions of real interest, as I shall show you.

This man was in his usual good health when, in 1879, for the first time he acquired gonorrhœa, which lasted for a month, and which was cured without complications. In 1882 he had a second attack, which was much more severe both as to symptoms and duration: it lasted from January until May. At the beginning of April of that year, about three months after the infection, he had considerable swelling of the left knee, with violent pains; shortly afterwards this passed up to the hip and also down to the heel of the same side; but the knee was the part most affected. The joint was immobilized, and vesication was employed, it seems; but it ended by his being confined to bed for six months, and for a further period of six months he was compelled to use crutches in walking about. Then came a period of walking with a cane; and finally, about the middle of 1883, he could walk without assistance. In January, 1884, he says he got another gonorrhœa, which was also long and tedious, and in a month afterwards the left leg was affected just as before; but he was able to go and take the mineral-water cure at Bourbon-Lancy (a hot spring of soda and iron water), where he was cured in a short time. He remained well up to July, 1885, when he got his fourth attack of gonorrhœa, and in July a new arthropathy occurred, this time of the right knee, followed in a few days by pain and great swelling in the right wrist, from which it went to the great toes of both feet, and afterwards to the heels, and then to the hip-joint. He was then brought to the hospital.

Upon examination, we find considerable swelling of the right knee, with the patella raised and the synovial sac distended with effusion; but there is no redness, and the pain is not very great. The metatarso-phalangeal articulation of the big toe is very painful and swollen, but the color of the skin is not altered. The little finger of the right side is in the same state, on the level with the same joint, as the toe (that is, at the articulation of the first phalanx with the second); the wrist is also painful, but there is no redness or swelling to be seen at present. As to the other side, strange to say, the left knee, which, as you remember, was the first affected, does not now show any symptoms, except that, on moving it, the articulation makes a crackling sound. His general health is not altered, the heart is intact, and the urine normal; the urethral flow persists, but it is not abundant, and micturition is painless.

We have here, then, the most perfect type of articular complications that gonorrhœa can produce. These blennorrhagic arthropathies have long been called *gonorrhœal rheumatism*, which is certainly a wrong title. If we look at the whole of this man's history, we can readily deduce from it a number of important and positive lessons that I will first of all present to you as propositions.

First. The absence of articular manifestations during an attack of gonorrhœa does not at all imply that there will be immunity from them in case of ulterior gonorrhœas.

Second. On the contrary, the presence of such articular manifestations during a gonorrhœa does imply the repetition of the same in case of further infection.

Third. The chances of articular manifestations increase with the number of attacks of gonorrhœa. This proposition, like the preceding one, is the expression of what has happened to our patient; for the interval between the commencement of his first attack and the appearance of the arthritis was three months. But it was only one month for the second attack, and less for the third: so that the predisposition increases with the repetition of the malady.

Fourth. Gonorrhœal arthritis often attacks only one joint; but it may be found in several, and that from the very first sign of its appearance.

Fifth. The small joints may be affected as well as the large ones.

Sixth. The treatment called "abortive," used in gonorrhœa, is not the cause of the arthropathy, for our patient has never been submitted to this form of treatment.

Seventh. The treatment used in gonorrhœa has no influence over the development of these arthropathies. He was always treated in the same way, and had no attack with his first gonorrhœa, but had with the three others.

These are the interesting conclusions we reach from the study of a single case. Now I should like to look at the history of these cases from a general point of view, and see what is the relation between gonorrhœa and these articular manifestations, and what other complications it is capable of producing. The sole cause of these arthropathies is true gonorrhœa, contagious and specific: the other kinds of urethritis cannot produce them. They are more frequent in men than they are in women (who can have them, however); and they are quite independent of any rheumatic diathesis. These arthritic troubles also have nothing to do with the abundance of the flow, as they will occur quite as often when it is copious as when it is ceasing. Nor do they present any regularity as to the time of their appearance: though they develop frequently between the sixth and fifteenth day, as Fournier has so well observed, they may come on much later, as the history of our patient shows. The truth is that your clients may be exposed to them as long as their gonorrhœas may last. All that I can admit from my observation is that the period from the second up to the fifth week is the one to be dreaded. The old idea that when the running ceases the arthritis shows itself is proved now not to be true, for it is rare that the flow is even diminished in volume in these attacks. Finally, these complications are more common in youth and in adult age than they are in after-life,—this is independent of the fact that gonorrhœa is more frequent in younger men,—for in old age the disposition to arthritis of this nature seems to be diminished, or at least attenuated.

The predilection of these arthropathies seems to be first for the knee; next the tibio-tarsal articulation; then the toes and fingers; and, lastly, the wrist, elbows, and shoulders. It is important to note that the vertebral articulations can also be affected. An English writer* assigns the first rank as to frequency to the elbow-joint; but this conclusion is not justified by the statistics of other observers. In two-thirds of the cases more than one joint is affected.

The clinical forms of the disease are not always the same. There are three principal kinds. In the first it is something like an acute hydrarthrosis, there are no general symptoms, and the local pain is more or less severe. The important point to be observed is that there is a *rapid effusion* into the articulation affected. In the second form, which is the most common, there are symptoms of an acute fluxion of one or more joints, and the pain is intense. The tumefaction is considerable, and it is due not only to the effusion, but also to a swelling of the extremities of the bones and the peri-articular tissues. There may be some superficial redness and local heat, or even a slight fever. While this form presents some analogy with acute articular rheumatism, it is essentially different; for, even when it is multiple, it never presents the general diffusion of rheumatism. It also has not the usual and characteristic mobility of rheumatism, for it fixes itself, and when a new joint is affected the others remain just as they were.

Again, there are none of the profuse sweats of rheumatic arthritis. Fever also is slight. When it does exist, which is rarely, it is of very short duration, and never rises to the thermal points that a rheumatic fever does. The urine also is not charged with uric acid products, as in rheumatism: so that the analogy to this last disease is merely apparent. The third form is constituted solely by pain, without swelling or deformity of the joints.

The *evolution* of these arthropathic affections is a very long one. In light cases they may arrive at resolution in four weeks; but this is the exception. The rule is that it will be months before the patients will recover the use of their limbs. Resolution also is not the only termination, for

* Davies Colley on "Acute Gonorrhœal Rheumatism." Guy's Hospital Reports, 1883.

Bradford twice observed anchylosis of the vertebral column.*

White swellings and endocarditis are further complications. The possibility of endocarditis was for a long time denied, but it is now perfectly well established. Indeed, it may occur directly from the gonorrhœa itself, when arthritis is not present, as Baudin proved in 1879; but it is of course more frequent in the articular disorder. It is, as a rule, light; but it can take on the character of infectious endocarditis.

The problem of the *pathogeny* of articular accidents in gonorrhœa has given rise to many theories; but they can mostly remain now among the historic souvenirs of the past. The only one that has obtained any credit is Laségue's idea that a purulent infection can act by reabsorption of the pus. Haslund in 1881, and Holst afterwards, published observations showing that a purulent infection from gonorrhœa can give rise to a general pyæmic state; and in this, gentlemen, lies the truth. Gonorrhœa, a local affection, can engender, by *reabsorption of urethral products*, an affection at a distance, such as the articular disease we are talking about. This interpretation cannot be contested to-day, for other proofs than the evolution of secondary accidents in the joints are now in our hands.

In 1879 Neisser discovered the special microbe of gonorrhœa, the gonococcus. These organisms color well with methyl-violet; they are large, round, rarely alone, mostly united in twos, giving the appearance of the organisms in the form of an 8 (the diplococcus). They are constant in gonorrhœa in women, as well as in men. Neisser found them even in quite old gleets, and also in gonorrhœal ophthalmia; they cannot be found in the other discharges of the urethra. This microbe is found in the interior of pus-globules as well as on their surface (contrary to what Neisser thought), and they also invade the epithelial cells, as Bouchard, Cornil, and others have shown. The drawings on the wall will show you the gonococcus as taken from our patient by M. Berlioz.

The specific action of the gonococcus, indirectly established by its absence in other liquids than the gonorrhœal pus, has been directly shown by Bockhardt and Welander. This last observer introduced into the urethra vaginal liquids with various forms of micro-organisms, but without the gonococcus, and he obtained negative results until he introduced them, when he produced this special microbe in all his cases. Its *migration* is also as well established, for Schedler † showed the presence of this form of microbe in the vegetations of the endocardium. Later, in 1882, Martin ‡ found them in purulent matters of blennorrhagic origin. The following year Petrone § saw them in the liquid taken from joints that were swollen. Again, Bockhardt, in 1882, introduced the fourth generation of a culture of this microbe into the healthy urethra of a man, with the result of a profuse production of the gonococcus.

We can conclude, then, that gonorrhœa is a local infection that is capable of generalization; hence, that it presents two periods: 1, local infection; 2, diffuse infection, whose effects may be seen in the eye, in the articulations, in the heart, and in the nerves, and particularly the sciatic nerve.

In regard to treatment, these precise notions of the nature of this malady have not had the influence on its therapeutics that might have been supposed. It would seem at first sight that the "abortive" treatment would be justified in all cases; but this is not so, for when one sees at least a drop of pus at the meatus, the lymphatics are *already full of the gonococcus*, which cannot be reached. Again, certain agents which were thought to have a destructive action on these microbes have been found by experiment not to kill them. The solutions of nitrate of silver, boric acid, iodoform, eucalyptus, and even corrosive sublimate are not found efficacious. Eklund found that a ten-per-cent. solution of the sublimate failed to destroy the gonococcus, which did not lose its power of movement for several hours.¶

The only antiparasitic agents the utility of which has been established are carbo-

lized water and chloral,—injections of one part to six hundred for the carbolic acid, and two to three hundred for the chloral; but all these measures need an internal treatment added as well; and this medication remains to-day what it has always been,—that is, copaiba and cubebs.

ORIGINAL COMMUNICATIONS.

REPORT ON RECENT PROGRESS IN GYNÆCOLOGY AND OBSTETRICS.

BY W. H. H. GITHENS, M.D.

PREVENTION OF PUERPERAL PYREXIA BY ANTISEPTIC VAGINAL DOUCHES.

A VALUABLE study of antiseptics in private obstetric practice, by Henry D. Fry, M.D., of Washington, D.C., appears in the April *American Journal of Obstetrics*. The measure of effect is by four thermometric observations each day. He does not use uterine injections, and resorts to one vaginal injection only, immediately after labor, unless the lochia become offensive. He is careful to cleanse the accoucheur's hands antiseptically. A rise of temperature at any time after labor he considers pathological, and "milk fever" a mild form of septicæmia.

ASPHYXIA OF THE NEW-BORN.

In the same journal, Dr. Geo. H. Noble, of Atlanta, Georgia, shows that asphyxia neonatorum, in some cases at least, depends upon anæmia of the brain, and can be relieved by holding the child up by the feet, the head hanging down.

TUMORS COMPLICATING PREGNANCY.

In the same journal is a report by M. Hofmeier, M.D., on Cæsarean section when pregnancy is complicated by tumors of the parturient canal. The prognosis depended largely on whether the patients came under treatment during pregnancy or not until during labor. In twenty-eight such cases during *pregnancy*, all the mothers and fifteen children were saved. In twenty-five cases of *labor* so complicated, fifteen mothers and twelve children died. In the twenty-eight cases treated during pregnancy, section was performed seven times. In one instance a uterine myoma was removed at the fifth month, pregnancy continuing to term with delivery of a living child.

CANCER OF THE OVARY.

E. Cohn, assistant at the clinic of Prof. Schroeder, has collated one hundred cases of malignant tumors among six hundred ovariotomies performed in nine years. He includes papillary cysts on account of their tendency to carcinomatous degeneration and frequency of return. In this his experience differs from that of Dr. Goodell, who has found them benign. Of these one hundred malignant cases, fourteen operations could not be completed, nineteen patients remained well at the end of one year, and three of these died subsequently of relapses.

Martin had observed only twelve malignant cases among one hundred and ninety-one ovariotomies. He ascribes this low proportion to his habit of removing ovarian tumors when very small.

VAGINAL HYSTERECTOMY FOR CANCER.

Of eighty total extirpations of the uterus through the vagina by Martin, only seven had died. Based on these statistics, Duevelius draws the conclusion that vaginal hysterectomy is the less dangerous operation. He gives an analysis of one hundred and thirty-eight cases of partial and total extirpation of the uterus for cervical carcinoma. In the first place, he divides carcinoma into three varieties: 1. *Epithelioma of the cervix*, with cauliflower excrescences and profuse secretion and hemorrhages. This form extends early to the vagina, but comparatively late to the uterus; hence remains local for a very long time. To this form partial extirpation is pre-eminently adapted. 2. *Adenoma of the cervical mucosa*, which tends less to new formation and more to ulceration; easily spreads to the body of the uterus along the mucous membrane, and leaves the vaginal cervix long intact. This form is slow in giving rise to symptoms. 3. Begins as a circumscribed cancerous infiltration of the tissues of the cervix, which is irregularly tumefied; and finally it ulcerates through towards the outside or inside of the cervix.

The latter two forms, as a rule, can be operated on with any prospect of permanent success only by the total extirpation, as they readily spread over the entire uterus and their limits cannot be at once determined.

Of the cases analyzed, twenty died; ten complete and ten partial. Of those treated by total extirpation (twenty-nine), one-half had relapses within a year after operation. After two years, one-fourth still remained well,—such result being a full justification of the operation as a means of prolonging life. Of those treated by partial extirpation (eighty-eight), forty-five remained well at the end of a year, and observation for five years did not greatly modify this proportion.

[A successful case of complete extirpation was reported by Dr. Wm. Goodell to the Obstetrical Society of Philadelphia, April 15, 1886.]

LAWSON TAIT ON OVULATION AND OÖPHORECTOMY.

In a lecture delivered by Mr. Lawson Tait in the University of Edinburgh, December 18, 1885, he stated as a well-known fact that, while menstruation occurs only at definite and regular times, ovulation may take place at any period, and it certainly is by no means so frequent as menstruation.

He gives as a frequent cause of salpingitis in young girls between the ages of sixteen and twenty, who are pure virgins, a chill after a dance, or sitting on damp grass after playing tennis.

He answers the objection urged against the removal of the ovaries as unsexing the patient by stating that the ovaries are generally small and are bound down by adhesions. The Fallopian tubes are found adhering to the pelvis and are frequently occluded. The patient is thus completely sterilized by the disease itself, and this fact removes the objection that surgical interference prevents any further impregnation; besides, the operation relieves the great pain and suffering. The dyspareunia is hereby removed, and thus operative procedure is the only possible way of resexing the patient.

He thinks catarrhal salpingitis a prominent agent in the causation of tubal pregnancy,—"spermatozoa going up the tube because they have no ciliæ to fight against."

Dr. Howard A. Kelly, in the Transactions of the Obstetrical Society for April 15, 1886, demonstrates by description and illustration the changes which take place in the relations of the tubes and ovaries as a consequence of chronic salpingitis and the extension of the inflammation to surrounding tissues.

THE REMOVAL OF TUMORS OF THE ABDOMINAL WALL, WITH THEIR PERITONEAL COVERING.

Sänger (*Archiv f. Gynäk.*, xxiv. 1), in a recent article, treats of the removal of tumors of the abdominal wall when the peritoneal covering is so closely adherent that it can be preserved only by such a difficult dissection as would leave a large thin sheet of peritoneum without good vascular connections. He removes the tumor, in one case which he reports, and brings the margins of the incision—muscle and skin—togther by sutures, and leaves the internal surface without any attempt to bring the peritoneum together. Sänger reports experiments upon animals in which he found that healing takes place and endothelium is formed as is epidermis after the destruction of skin.

INFANTILE JAUNDICE.

H. Quincke (*Archiv für Experimentelle Pathologie und Pharmakologie*, xix. 1, 2) maintains that the common form of infantile jaundice is due to the continued patency of the ductus venosus. During fœtal life the blood of the portal vein contains no bile-pigment, as no digestion takes place and but little bile enters the intestine. After birth, bile is poured into the intestine in large quantities, and a portion is absorbed by the portal system of veins and conveyed to the liver, where it is separated from the portal blood. Should there, however, be a delay in the closure of the ductus venosus, a portion of the portal blood containing bile enters the general circulation through the open duct, and gives rise to a more or less intense jaundice, which disappears on the contraction of the duct.—*Med. Times and Gazette.*

ATTITUDE OF THE PARTURIENT WOMAN.

In the *American Journal of Obstetrics*, June, 1886, is an article by H. B. Hemenway, M.D., strongly recommending a sitting position during labor. Among others, he gives the following reasons. Gravity, bringing the vertex more firmly on the os, increases the force of the uterine contractions from reflex influence. The upright position favors the formation of a large "bag of waters" in advance of the fœtal head, thus facilitating the dilatation of the os uteri and the soft parts, and preventing friction between the fœtus and the partu-

rient canal. The position of the woman should be so arranged as to increase the lumbar curve, thus throwing the fundus of the uterus forward, that the contractions of the abdominal muscles may be thoroughly utilized. The article is ably written and is well illustrated.

RETROVERSION AND FLEXION OF THE UTERUS.

At the November meeting of the Obstetrical Society of Philadelphia, Dr. Howard A. Kelly read a paper upon a new method of curing "vicious" retroversion and flexion of the uterus that could not be relieved by pessary, tampon, intra-uterine medication, or any of the ordinary methods of treating that trouble. The plan was to secure the cornua of the uterus by means of sutures to the abdominal wall, at least two inches above the pubes, to allow for distention of the bladder. He had adopted the method in one case in which he had previously removed the appendages for ovarian disease. The result was very satisfactory. Communications concerning somewhat similar operations from Keith, Tait, and Sänger were read. The paper will appear entire in the *American Journal of the Medical Sciences*. The name suggested for this operation is *hysterorrhaphy*.

OBSERVATIONS ON SOUTHERN CALIFORNIA AS A RESORT FOR PULMONARY INVALIDS.

Read at Binghamton, New York, before the New York State Medical Association, June 17, 1886,

BY THERON A. WALES, M.D.

THE search for the Fountain of Youth was but a primitive expression of desire to renew the failing functions of these mortal bodies by some mysterious, because far-away, source of recuperation. Science cut down that hope; but it has sprung afresh in every age, growing upon a perhaps more rational but hardly more substantial basis.

One of these articles of later belief, to which science has given at least quasi approval, has been the assertion that all pulmonary invalids could and would be restored if the sufferer should be placed in the proper climate as regards purity, moisture, elevation, and temperature; and of late years much time, thought, observation, and critical examination has been given to the demonstration. To a body of trained medical gentlemen I need not stop to explain how far this is from being the whole truth; but I observe merely that it seems popular in proportion to its incompleteness.

At one time or another, various parts of our union of States have been extolled as the point where the sufferer from pulmonary difficulties would find relief and restoration of health, and therefore prolongation of days; and thither the annual army of such sufferers has wended its hopeful way, in too many cases to be returned in narrow coffins to former homes, silent witnesses that even "the finest climate in the world" cannot do everything.

At one time or another, Minnesota, Florida, Colorado, and even Texas, has attained pre-eminence in such matters; not to mention the similar claims of the Adirondacks, the western half of North Carolina, and Eastern Tennessee, as well as some other portions of the Southern States, and the lake regions and pine woods of the State of Maine.

It is not my purpose to discuss in this paper how much climate may or may not do for pulmonary complaints, but to assume that, under proper regulations, climate may be of great advantage, and, therefore, to examine Southern California with that point in view.

It was the fortune of the writer to spend the months of January, February, and March of the present year in the southern half of California, and, as he went purely for observation and adventure, he had no bias to tincture his opinions either for or against the country as a resort for pulmonary sufferers.

The northern limit of observation was about the Bay of San Francisco, the southern at San Diego; while, width-wise, he saw varied and various points from the Sierra Nevada to the Pacific sea-beach. At all points he met and conversed with so-called consumptives, varying from the professional dyspeptic—who always expectorates in his handkerchief and then minutely examines it, and who manages to worm out of you, as soon as he learns you are a physician, an "unofficial" opinion of his case *without cost to himself*, and then triumphantly refutes it by telling you what Dr. Blank said was the matter with him that very morning—to the poor, hopeless, hollow-eyed, hectic sufferer whose ringing cough echoes nightly through the

long corridors of every hotel on the Pacific coast, and who always thinks he must have taken a little cold the day before.

The Southern California coast-line impinges upon the Pacific Ocean at an obtuse angle, of which Point Conception is the apex. All of California north of this point, so far as the coast is concerned, is absolutely harmful to pulmonic sufferers. South of it is the land of blessing, if the disorder of the lungs be one susceptible of improvement from sea-air. North of this point along the coast comes in the morning the damp sea-fog, chilly and depressing; while in the afternoon the fierce acrid northwest wind completes the mischief the morning fog began. It is no climate for irritable lungs, and should be carefully avoided by such sufferers.

Roughly speaking, Californian topography can be divided into the Sierras or mountains, the Mesa or table-lands, and the coast-region or sea-side; but in detail there are to each of these sections accidental surroundings which so modify the climate that in no country in the world can you find such numberless varieties of climatic conditions as in this Golden State. Therefore it is that the invalid seeking health on the Pacific coast has need to know where and why he should seek some particular location.

In general terms, again, the high altitudes are advantageous to those whose lungs are small, weak, or partially collapsed; the Mesa and foot-hills, to those of a catarrhal tendency; while the coast furnishes, with its increased moisture and saline quality, a soothing, equable air for many whose respiratory surfaces are hot, dry, and irritable. * * *

I am reminded here to speak of a failing, examples of which were never wanting among the seekers for health on the Pacific slope,—a failing of family physicians in regard to those patients whose lungs have exhibited tendencies to disease too obstinate to be successfully overcome. It is unpleasant to have patients die. It is painful to lose those who generally are more than patients, are warm and admiring friends; too often those whom we have welcomed at birth, have guided through the diseases of infancy, and have watched over as they developed into young men and women, only to see them fall victims of that arch-enemy, pulmonary phthisis.

I fear that at times some of us have found it easy to evade the final struggle with the great destroyer by recommending the patient to try a "change of climate," and have added, to accelerate the departure, "that whatever change was made had better be made promptly." And so the poor sufferer, not infrequently a frail girl, is bundled off, it may be to California, because "John had heard that Andrew said that James had written home that Peter's wife's mother, since she went to California, has got strong and well, notwithstanding the fact that the doctor had said her lung-trouble would never be any better." No knowledge, mind you, of the diagnosis or exact condition of Peter's mother-in-law's lungs; no knowledge as to whether the cases are similar; no precise knowledge even of her own lungs, further than that the doctor said her lungs were "somewhat affected," and that she had better try a change of climate; no knowledge of the climate to which she is going; no knowledge of anything except that, whereas she now is failing, she has an expectation that the mighty climate of California is miraculously to restore her to health. And so, some day, travel-stained and weary, with perhaps a single companion, she is landed at a hotel on the Pacific coast, placed in a lonesome, sunless room, with no means of heating, in a climate where to sit in the shade is to take cold invariably, and literally left to herself. That night comes up a furious norther,—for even on the much-lauded Pacific coast come up furious northers,—and the unfortunate invalid wakes in the morning to shiver with cold in the finest climate the world ever saw. With insufficient clothing, because she was going to a warm country; with no fire; timid and unaccustomed to travel; unable to get anything without feeing the waiters; homesick and forlorn, what wonder she soon takes to her bed, sick and sorrowful? And even then, when she asks for a physician, ten to one but that the employee who is sent to call one is in collusion with some humbug, and for a percentage places her in the hands of a quack. You can imagine the rest; I do not need to dwell. Some day her lifeless form is returned to sleep in the quiet churchyard of her native village. A victim of what? Of the California climate? By no means. I implicitly believe that the California climate, suitably selected, can do more than any

other one thing for the relief of pulmonary sufferers.

No, not a victim of the over-praised climate; but a victim first of the neglect or carelessness of the family physician to properly inform her or her friends of the exact physical condition, and to furnish proper instructions as to the surroundings most favorable for an ultimate recovery; whether at a high altitude or a low one; whether in a moist or a dry air; whether near the sea or remote; and many other details which easily occur to you, but which I will not here take time to record; and, most of all, to have sent with her a careful diagnosis of the case, with a history of previous attacks, etc., for the guidance of any honest physician under whose care she may come. A victim also of that too general but fallacious belief of people that there exists somewhere, not a fountain, but a marvellous climate, which will cure universally every sick one who shall come to breathe its health-giving air.

A victim, furthermore, of those conscienceless, rapacious, predatory rascals who fatten upon the credulity of suffering humanity, and who throng in Southern California, and particularly in Los Angeles, as thickly as the gray wolves of the plains upon the heels of a wounded elk. * * * These are but a few of my observations.

Nevertheless, Southern California is the most excellent place yet found for the relief of those sufferers whose trouble is of a pulmonary character; the best unaided agency in the world for the restoration from pulmonary disease, when the situation is properly chosen.

ELMIRA, NEW YORK.

REPORT OF A CASE OF SPLENIC LEUCOCYTHÆMIA.

Read before the New York State Medical Association, Third District Branch, meeting at Binghamton, June, 1886,

BY E. LESTER, M.D.,
Seneca Falls, New York.

THIS disease, as described by His, Gowers, and other writers, is characterized by a permanent increase of the white corpuscles in the blood, the tint of which is, in consequence, paler than in health.

To refresh your memories of the character of the disease I will give you a synopsis of the symptoms as laid down by these writers before I describe my case, which I consider well marked in every respect.

The glandular system is affected, although not so much as in Hodgkin's disease: still, the mesenteric glands become enlarged in most cases. Heredity, sex, age, and conditions of life have an influence in causing this disorder. Malarial influences stand at the head in producing this disease. The first symptoms are splenic pains and abdominal enlargement. These are followed by weakness, languor, pallor, digestive disturbance, dyspnœa, excessive and unnatural appetite, vomiting, and diarrhœa. Hemorrhage from the nose, as the disease progresses, is almost a constant symptom. Noises in the head, deafness, pain in the back of the neck, priapism without passion, are among the most prominent symptoms.

The average duration of life is about two years.

The case I have to report of this disease was a young man, aged 18 years, American by birth, of healthy parents; born in the country, and living on a farm in a non-malarial section till he was fourteen years old, when his parents came to Seneca Falls with him, their residence being on the bank of Seneca River. At the age of fifteen he had malarial fever, which assumed the form of ague, and when he was sixteen, in the summer of 1884, he had typho-malarial fever, and was confined to his bed for some weeks. He resumed work after that sickness till the spring of 1885, when he was taken sick with pain in the back of the neck and general weakness. I was called in council by his attending physician, and found that the most peculiar symptom in his case was priapism.

His penis was erect and full, the corpus cavernosum bulged, the corpus spongiosum full and firm, so that the organ could not be bent. We looked for a cause; there was no tenderness along the spine, only pain at the base of the brain, and that only at times. Warm baths were used so that he could empty his bladder; the doctor said he could not introduce a catheter, but after a warm bath he could evacuate his bladder by getting on his hands and knees. His pulse was slow; his skin dark and leaden-colored; spirits low, with fear of death. The doctor told me he tried everything to relieve him, but the priapism did not leave him till the end of ten

weeks. I saw him only once, at that time. In September, 1875, they brought him to me. His abdomen was then greatly distended; his color pale and dusky; his eyes dull; so deaf you could hardly make him hear; his gait was unsteady; breath short and difficult; the arteries above the clavicle beat so you could see them across the room; said he had frequent nose-bleed; an enormous appetite; slept a great deal.

I then took the case. I gave him mercurial cathartics and followed with quinine in pretty large doses, and he seemed to improve for a few weeks; but all of his bad symptoms returned; his abdomen increased so much that I introduced an aspirator-needle, but not a drop of fluid did I get. His feet and legs swelled; he had iritis in his left eye; his testicle swelled and was very painful; his nose-bleed came on every day, with the pains at the base of the brain; he lost his appetite; could not sleep; was very restless; nose-bleed so severe I had to keep the passage plugged all the time till death came, February 17, 1886, from exhaustion.

Post-mortem held February 18; made an incision in the median line. The whole abdominal cavity seemed filled with the spleen and liver; there was no fluid, no adhesions; the stomach was distended; the liver and spleen had pressed the diaphragm up to the fourth rib; the heart was pressed to the right and nearly horizontal. Removed the liver and spleen. The liver weighed fourteen and a half pounds, and the spleen seven and three-quarter pounds. The left kidney was nearly seven inches long and three in width; the other was a little above the normal size.

The points of interest in this case are the long duration of the priapism (ten weeks), the great weight of the spleen (seven and three-quarter pounds), and the size of the liver (fourteen and a half pounds).

OXALURIA.

Read before the New York State Medical Association, Third District Branch, at the Meeting held at Binghamton, New York,

BY A. R. NICHOLSON, M.D.,
Madison, New York.

WITHOUT attempting in this paper any originality of thought, it is my purpose merely to bring to your notice a group of patients that to me in a brief practice has been quite a large one, and after an understanding of the case and a correct diagnosis, with appropriate remedies, I have found very amenable to treatment.

The sex of those that have come under my observation has been principally the male, although I am not prepared to state that man as the rule is more liable to be affected than woman.

These patients are not ordinarily termed sick,—that is, are not confined to their room or house,—and are able to be about; yet they are incapacitated from attending well to their vocations. They are not even in possession of good enough health to enjoy life, but, on the contrary, complain of a disturbance of the nervous system; feeling irritable, dejected, and melancholy, with a loss of ambition, and disinclination to attend to any slight duty which may devolve upon them. They are unreasonable in their desires and demands, finding, as they say, "there does not anything go right."

Their business, if they have any, becomes dull and irksome; there is a desire to absent themselves from it, and to avoid society, preferring to remain alone and brood over their bad feelings.

In two cases the patients confessed that they had felt a desire to rid themselves of their bad feelings by committing suicide, but lacked energy or courage to do so.

The physical sufferings are usually those of severe headache. The patient imagines that his brain is diseased, or at another time he may have a feeling that his heart is affected, and wish that organ examined. But more frequently attention is called to pain through the loins and abdomen, with an occasional pain in the thighs. I have also noticed a frequent desire to micturate, and a sense of heat accompanying the passage of the urine. The stomach is usually deranged, and there is a consequent loss of appetite, with an accumulation of gases, which disturbs the patient by frequent eructations, and a degree of emaciation results.

In alluding to this class of cases I refer to the condition known as oxaluria. Upon an examination of the urine of such a person, a few or many octahedral crystals of the oxalate of lime will generally be detected, which can be found readily with the aid of a microscope with a magnifying capacity of four hundred diameters and of good defining power. The urine

usually is devoid of any other abnormality except an excess of earthy phosphates.

Such cases, although not presenting a very sick appearance, demand the serious attention of the physician. In order to benefit the patient, there needs to be found out the cause leading to this condition, which is frequently indigestion: the food is but partially fitted for absorption, and the processes of oxidation are retarded. In these cases the cause of the indigestion must be sought and treated. It may be that the patient's food is not of the right kind; it may contain so much starchy material that all of it cannot be completely oxidized, or the person may be breathing impure air, and the blood may not contain sufficient oxygen to oxidize a proper amount of food. The conditions under which the patient lives must be investigated. Too close application to business, with insufficient out-door exercise, or too small a quantity of water that is free from lime, may aid in causing it.

For the purpose of assisting in the oxidation of the food and stimulating the action of the liver on the food, nitro-muriatic acid, in five-drop doses well diluted and taken through a glass tube, after meals, serves the best of any medicinal remedy that I have used. This forms a pleasant drink, that most patients take with a relish.

A very important part of the treatment consists in relieving the patients of anxiety attending their condition by directing the attention to other objects, out-door sports, or active employment in the open air, and by freeing their minds of business cares for a period, until the oxalates can no longer be detected in the urine.

By following this mode of treatment, I have been enabled to relieve my cases completely of their physical sufferings, and those due to imagination readily vanish.

TRANSLATIONS.

Ignipuncture as a Method of Surgical Treatment of Chronic Cervical Adenitis.—Dr. Dumenil, Professor of Surgery at Rouen, reports nine cases of enlarged glands of the neck among soldiers treated by the introduction of a platinum wire into the gland and the practice of galvano-cautery. In some cases there was a discharge of caseous matter and free suppuration for a few days; in others this did not occur. In both groups of cases the glands rapidly underwent resolution, and only a trifling scar was left by the operation.

Although the most radical and rapid method of removing these glands would be by the surgeon's knife, which may now be done with antiseptic appliances even by the most timid, there still are cases in which deep cauterization has the advantage: for instance, where the patient recoils from ablation, or where the tumors are multiple. In case of doubt as to the malignant character of a tumor in these regions, probably prompt extirpation would be the most advisable plan of treatment.

At the present day this affection is no longer considered as a strumous engorgement or scrofulous adenitis, but as a local tuberculosis. The lymphatic glands of the neck receive the lymphatic vessels coming from the buccal, nasal, and pharyngeal cavities, and are specially liable to receive infectious particles which are carried by the air. The numerous diverticula which are met with in these regions, and the frequent lesions particularly of the gums, constitute ports of entry into which the infectious elements may enter with the greatest facility. The marked frequency among soldiers is due partly to bad hygiene, and particularly to neglect of the bucco-pharyngeal cavity.

As the affection is found very frequently among quite vigorous subjects whose general health is good, and in whom no hereditary predisposition exists, it appears evident that the local conditions are quite sufficient to explain the production of tuberculous adenitis.

In making the cauterization, a filiform galvano-cautery surmounted by a button was first employed, but afterwards was replaced by a simple platinum point, which was made to penetrate to the centre or traverse the tumor in one or more directions. Cold compresses were then applied. Anæsthetics were not needed. In all the cases except one the ignipuncture gave satisfactory results. The exceptional case passed from observation without having shown any diminution in the glands, but his general health remained good.

In almost all the cases the glands were in the way of becoming caseous, and it is

in this condition that good results have been the most rapid and the most striking. It would be interesting to know whether the cure was radical in these cases, or whether they afterwards suffered with visceral lesions due to infection. This question, which is of great importance, remains for subsequent investigation.—*La Normandie Médicale.*

Antifebrin.—Drs. A. Cahn and P. Hepp, assistants in Kussmaul's clinic at Strasburg, having made a series of observations of the action of the neutral substance acetanilide, or phenylacetamide, declare that it possesses remarkable power in controlling abnormally high temperature. This property is so characteristic that they propose its use in medicine under the title of antifebrin. It is a white, crystalline, odorless powder, slightly pungent to the taste, freely soluble in alcoholic liquids, and soluble in hot water, but almost insoluble in cold. It does not combine with either acids or bases, and, although a derivative of aniline, is itself non-poisonous in comparatively large doses, either to the lower animals or man. In cases of typhoid fever, erysipelas, acute rheumatism, phthisis, leucæmia, pyæmia, and pneumonia, to which this agent was given in doses of from four to fifteen grains (not more than thirty grains daily), decided effects were obtained upon the course of the fever. With the lowering of the temperature there was a decrease in the frequency of the pulse, but an increase in volume. Some unusual thirst or diuresis was observed for a few hours after the remedy was administered, but there was no chill and no vomiting.

The drug is efficient in about one-third of the dose of antipyrine. Its other advantages are that it perfectly agrees with the stomach, and that the diaphoresis is moderate in quantity. Special caution is enjoined to employ only the pure drug. It is a matter not only of theoretical interest, but also of practical import, that while others of the recent antipyretics are either phenols (such as carbolic acid, hydroquinone, resorcin, and salicylic acid) or bases of the quinoline group (including quinoline, kairin, antipyrine, and thallin), in acetanilide we have a body of quite different chemical constitution which exerts a similar effect.—*Centralblatt für Klinische Medicin.*

The Disinfection of the Hands.—After making a post-mortem examination or attending a case of puerperal fever, it becomes a question of great importance how to disinfect the hands thoroughly before attending another parturient woman. From experiment with gelatin cultures, it was found that if the hands are brushed with a solution of carbolic acid (three to five per cent.) or one of thymol (six per thousand), or in corrosive sublimate (one to a thousand), or if washed five minutes with soap and warm water, then brushed for two minutes with dilute chlorine solution, they are thereby perfectly disinfected.—*Revue Int. des Sciences Médicales.*

The Obstetric Bandage.—Professor Czerny, of Heidelberg, attributes the pendulous abdomen of some women who have borne children to the want of proper bandaging after labor. Observation has shown that the shape of the abdomen and the tone of the abdominal muscles are decidedly improved by the use of the obstetric binder, not only during the first week, but also for several weeks after confinement.—*Centralblatt für Gynäkologie*, No. 3, 1886.

Anisic Acid, a New Antiseptic.—By oxidation of oil of anise, anisic acid is obtained, which is isomeric with methyl-salicylic acid and has germicidal properties. The anisate of soda does not disagree with the stomach, reduces temperature, and increases intra-vascular pressure. It may be used in surgery as an antiseptic, or in the treatment of acute articular rheumatism as a succedaneum of salicylic acid.—*Revue de Thérapeutique Méd.-Chir.*, No. 15.

Chloasma.—Aguilar recommends the following:

Goa powder, 3 parts;
Acetic acid, 2 parts;
Benzoinated lard, 35 parts. M.

Three applications to be made daily.—*Revue de Thérapeutique Méd.-Chir.*, No. 15.

Painful Uterine Contractions in Parietal Myoma.—P. Ménière has found the following very efficient:

℞ Acid. citric., 0.25;
Narceinæ, 1;
Ext. viburni prunifolii, 2;
Syrupi, 250. M.

Dose, a dessertspoonful every two hours until the pains are relieved.

EDITORIAL.

CLINICAL ELECTROLYSIS.

THE solvent action of the electrical current upon both normal and abnormal tissues of the human body has come to be an interesting and important therapeutic study. That the current has a decided chemico-physical effect when used by galvano-puncture in an aneurismal sac, or within a nævus, has long been undisputed, but the claim that it exerts a solvent action upon ordinary inflammatory deposits has not been so generally recognized. This slow recognition is due, we think, to two causes. First, the advocates of the method have been carried away by their enthusiasm rather than led by patient observation, and their reports are often lacking in the fulness of detail, patience in trial, and candor of statement which are necessary to insure their acceptance. Secondly, the sceptics who have essayed to test the method have been still more deficient; for, in addition to the biassed state of their minds, they have often been absurdly lacking in expert knowledge and skill in the use of electricity, without which success is impossible.

At a recent meeting of the Philadelphia County Medical Society a paper was read by Dr. J. Hendrie Lloyd embodying the results of a very careful and prolonged trial of electricity upon inflammatory deposits in the female pelvis. The chief points brought out by this paper may be briefly summed up as follows:

The term electrolysis, as applied to this process, is probably in part a misnomer. While true electrolysis no doubt contributes somewhat to the result, it is certain that the resistance encountered in the mucous membrane, and the consequent diffusion of the current, do not allow of as great a concentration of electric force upon the diseased tissues as would be necessary to secure perfect electrolysis. This objection is, of course, removed in those cases in which it is possible to use a needle as one electrode and to puncture the tissues. This, we believe, has been done by Dr. Baker in one case of cellulitic deposit, but in the great majority of cases of pelvic cellulitis and stricture of the male urethra it would be neither practicable nor safe. The writer of the paper believed that electrical osmosis and the secondary action (chemical) of electrolysis, as well as counter-irritation, probably, all contributed to secure the result.

The dose of electricity ought in every case to be measured by a reliable galvanometer. This is necessary, first, in order to establish accurate data for subsequent deductions and future trials; in other words, to make the process strictly scientific. Again, the safety of the patient and the convenience of the operator demand this precision. This was emphatically shown in one of Dr. Lloyd's cases, where, in spite of careful observation, damage was done to the vaginal tissues. This will be impossible when the average safe dose is known and recorded; and these observations do much to indicate this average. Without measurement, and with the electrode out of sight, the operator cannot know whether he may not be doing too much on the one hand, or not enough on the other. The essential thing is to obtain the proper *quantity* of electricity. The particular *form* of galvanic cell from which it is obtained is of secondary importance. Every cell will give a quantity of electricity in exact relation to its volt force and the external resistance. If they are weak cells, more of them will be needed. The problem is strictly accord-

ing to Ohm's law, and the record is kept by a galvanometer.

The results obtained in these cases were encouraging. The evidence of absorption of inflammatory deposits was well supported, while the relief to many secondary symptoms was great. The details are as exact and complete as they can be made with our present knowledge. The paper was preliminary to a report which the writer intends to make upon the practice of electrolysis upon various diseased conditions. These cases were selected, first of all, because of the comparative ease of observation.

SOME RESULTS OF PASTEUR'S TREATMENT FOR HYDROPHOBIA.

ON October 31, 1886, one year and five days after M. Pasteur first advocated the practice of inoculation as a cure for hydrophobia, two thousand four hundred and ninety persons who were bitten by animals, rabid or supposed to be rabid, had received treatment in Paris according to his new method. The applicants from France and Algiers alone numbered seventeen hundred. In ten of these the treatment was unsuccessful in preventing the fatal result; in two cases death was directly attributable to delay in beginning the inoculations. Excluding these two, therefore, the deaths among the French subjects treated were one to one hundred and seventy: less than six-tenths of one per cent.

M. Pasteur thinks it probable that but few of the persons bitten by mad dogs in France during the past year had failed to apply at the laboratory in the Rue d'Ulm for his treatment; and yet of this comparatively small number who were not treated seventeen died with hydrophobia.

In the preceding five years sixty persons died with hydrophobia in the Paris hospitals: an average of twelve per year. During the past year there were in these hospitals of Paris only two deaths recorded as due to this disease, and in neither of these had inoculation been practised.

M. Pasteur has recently modified his method somewhat, so that now, in cases of wounds of the face or severe bites generally, the inoculations are repeated at more frequent intervals. He claims that immunity is thus attained earlier.

Assuming these statements—made before the French Academy of Medicine on November 2—to be true, it would seem that the great French chemist and man of science has finally established his method upon a secure foundation. Sciolists who contest M. Pasteur's method upon merely theoretical grounds would do well to study the figures above given. If they rest upon errors of observation, they should be exposed. If his statistics are correct, doubt seems no longer permissible. At all events, M. Pasteur has thrown the gauntlet into the arena in claiming that his method has received the endorsement of clinical experience, and that his hypothesis as to the power of anti-rabic inoculation to check the development of the dread disease—even when performed subsequently to the infliction of the injury—has been firmly established upon an experimental basis. Accepting the facts to be just as they are stated, the demonstration seems to be complete of the propriety of resorting to this treatment in cases unquestionably bitten by an animal known to have hydrophobia. As to the *modus operandi* of the remedial method, it remains an unsolved problem, with regard to which we confess ourselves very much in the dark.

THE RESULTS OF DR. SHAKESPEARE'S RECENT INVESTIGATIONS UPON CHOLERA.

ON the 18th instant a special meeting of the College of Physicians of this city was held in order to hear a lecture upon Cholera by Dr. E. O. Shakespeare,

who has recently returned from a tour of investigation by special appointment of the United States government. During his stay abroad he made personal visits to those whose labors have rendered them distinguished in this field; not only in several countries in Europe, but also in India. In commencing his review of his work, at the College, Dr. Shakespeare gave brief accounts of recent epidemics of cholera in the different countries where it had been studied, and illustrated his remarks by diagrams of morbidity and mortality. The connection between the outbreaks of the disease and infected water-supply was clearly shown in nearly every instance.

Although the proof of the statement that the comma-bacillus is the active and efficient cause of cholera Asiatica was not entirely satisfactory to his mind, the lecturer felt no hesitation in declaring that Koch had conferred an inestimable boon upon the race by placing in the hands of every practitioner an infallible means of diagnosis of this disease from cholera morbus and other diseases resembling cholera. He expressed the opinion that a health-officer or physician who, in the presence of suspected cases and before the prevalence of the malady as an epidemic, should fail to employ this means of deciding whether or not the disease is genuine cholera, would be guilty of criminal negligence.

After a personal visit to Ferran, in Valencia, and an examination of his methods of investigation, he was prepared to endorse the verdict of the French Commission with regard to the condition of his laboratory, but as to Ferran himself he arrived at a different conclusion. He was impressed by his modest bearing, and believed him a cultured gentleman, possessed of no mean skill as a bacteriologist. In his laboratory Dr. Shakespeare found as pure cultures of the comma-bacillus, and as handsomely mounted and stained specimens, as could be found anywhere in Europe. A few of these slides, made in his presence, were exhibited after the lecture was finished.

With regard to the result of Ferran's inoculations, Dr. Shakespeare demonstrated by the official returns made by the government officers, who are not friendly to Ferran, that there was a sudden and marked reduction in the number of cases and in the mortality in several villages after the inoculations were begun,—this measure apparently having about six times the value of ordinary hygienic precautions in checking the epidemic. The facts concerning inoculation, so far as they have been reported officially, seem to indicate the importance of making, in future epidemics, this method the subject of a searching scientific investigation, such as it has not received up to the present time.

A GERMAN MEDICAL SOCIETY IN PHILADELPHIA.

AT a meeting of German-speaking physicians of this city, held recently, it was decided to form a new medical society, the objects of which would be to afford a means of increasing the knowledge of the German language and medical literature on the part of its members, and in general to serve the ends of advancing medical science by holding monthly meetings for the reading of papers, the reporting of cases, and discussing questions of interest which properly would come before such an organization. Ferdinand H. Gross, M.D., of the staff of the German Hospital, was elected temporary chairman, and a meeting for organization will soon be held, at which the charter, constitution, and by-laws will be submitted by a committee appointed for the purpose, which is now engaged in translating the constitution of the Philadelphia County Medical Society into German, with a probability of its adoption as the organic law of the new society. The proposed association has every prospect of a useful career. We heartily wish it success.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE matters of greatest interest here at the present time are those involved in the opening of the medical schools. We have eleven fully-equipped medical schools in London, not including the London School of Medicine for Women, which is also fully equipped. In the provinces there are eight medical schools: four connected directly with universities,—viz., Cambridge, Oxford, Newcastle, and Owens College, Manchester,—and four which have no such direct connection,—viz., Bristol, Birmingham, Leeds, and Sheffield. Of these, the last-named has not in recent years published any returns of the number of students entering, and the schools at Bristol and Birmingham have always been small. Cambridge is by far the largest English school outside London; Owens College stands next; and then, at a considerable distance, follow Newcastle (connected with the Durham University) and Leeds. The Oxford Medical School has only begun serious work as a completely-equipped school this session. Twelve students have joined this term, and I understand that twenty-one students in all are at present dissecting. Considering all the circumstances and the peculiarly strong opposition to the adoption of medical studies which seems to be offered by the *genius loci*, this must be considered encouraging evidence of the tendency among the class who go to Oxford to take up the study of medicine. The physiological laboratories, under the direction of Professor Burdon Sanderson, are now in order, and a new dissecting-room, with accommodation for seventy students, has been taken into use at the beginning of this term.

The number of students entering the medical schools in London this session shows a slight falling off. A considerable improvement was noted last year, but this has not been maintained. In 1884 the number entering was 587; in 1885 it was 647; and in 1886 it is only 623. As several of the schools which suffer most, notably Charing Cross, Westminster, and the London Hospital, have expended large sums of money in rebuilding their laboratories, lecture-theatres, and other buildings, this failure to obtain a larger "entry" is peculiarly disappointing. St. Mary's Hospital is the only school which appears to be winning a new reputation, though it may be noted that both Guy's Hospital and University College seem to be regaining the popularity which for a time they had lost.

The decline in the popularity of London as a medical centre can hardly any longer be disputed, and is causing many searchings of heart. Very various explanations are given for this phenomenon; but the one which finds greatest favor is that which attributes the decrease in the numbers to the absence of any facilities for London students to obtain the title of M.D. The University of London exacts a long curriculum, and unless a student becomes an undergraduate of that university before the commencement of his student-career, its degrees are forever beyond his reach. At present there is practically no alternative. Many London students obtain degrees from Durham University; but to do this they must, for the time at least, cease to be London students. Indeed, nobody any longer denies that this is a hardship, and at least three schemes have been propounded to remedy it. By one it is proposed that the London University should modify its requirements so as to meet the necessities of average students; another owes its existence to the Association for Promoting a Teaching University in London, and practically involves the creation of a new university compounded out of the various teaching colleges "of university rank" at present existing in London; the third is the proposal that the Royal College of Physicians and the Royal College of Surgeons, which, under a temporary arrangement, recently formed a conjoint examining board to grant a double diploma in medicine and surgery, should conjointly obtain a charter empowering them to grant the degree of M.D. It is this last scheme that seems most likely to be realized: it has a persistent and influential advocate in Sir William Jenner, the President of the College of Physicians, and if the conjoint committee which is at present at work can agree on a good working constitution, it is highly probable that the charter will be obtained.

In this connection it is curious to note that Mr. D'Arcy Power has shown, in a recently-published historical work chiefly founded on materials left by the late Mr. Flint South, that such a union between the two colleges existed several centuries ago, but, after lasting about fifty years broke down. Whether Mr. Power's discovery is an argument for or against the present scheme I must leave to others to determine; but, as it stands, it certainly seems to cut both ways.

A serious difficulty has arisen, however, in connection with the Apothecaries' Society, which has the statutory right to grant a license to practise medicine. It has applied to be allowed to join the Colleges of Physicians and Surgeons in the formation of a conjoint board, and has so far been refused. The final decision has not yet been taken; but should it be adverse there would be a risk that the Apothecaries' Society would presently die of inanition. This would not in some quarters be regarded as a misfortune. It has, however, been recently pointed out that the Society is the only body which possesses any effectual powers for the suppression of quackery or any form of unlicensed

practice. A good deal of practice is done by chemists and druggists, who prescribe over the counter and in some cases visit their "patients," by bone-setters, and by herbalists. It is only when the patients die and the necessity for giving a certificate as to the cause of death arises that these gentry are liable to find themselves within the clutches of the law, and, as a rule, they have sufficient address to avoid the scandals and publicity which official inquiries involve.

The wide-spread belief that there is some connection between the tonsils and the testicles, and that excision of the former may induce atrophy of the latter, did not meet with any support during a discussion which arose at the Clinical Society on October 8. Mr. Pearce Gould showed a young man, aged 27, over six feet high, tall and slender, with smooth, hairless face and a boy's voice, in whom the penis was small, the testicles very small, the prostate almost and the seminal vesicles quite imperceptible per rectum; the tonsils were very small. He combated the theory which would have traced in this case a connection between the small testicles and the small tonsils. He said that in Zanzibar all boys had their tonsils removed, and yet the Zanzibarees had not small testicles, and were as fertile as other folk. As the operation of excision of the tonsils had become so common, he thought that, if it had any such influence as was supposed on the testicles, this fact would now be well established. Dr. Felix Semon supported Mr. Gould, as did all the other speakers.

The Royal College of Physicians have received two thousand pounds under the will of the late Gavin Milroy, one of the earliest workers in sanitary science. He was a member of the commission sent out to the Crimea when the mortality among the British soldiers during that most fatal campaign was at its height, and it was to the reforms introduced by this commission that the decrease in the mortality was attributed. Dr. Milroy left the above-mentioned sum for the endowment of a lectureship on public health and sanitation. The arrangements are not yet complete, and in making them the College will have the advantage of considerable experience; the three courses of lectures which have been delivered for so many years have been, on the whole, successful, and the reason has doubtless been that the widest latitude has always been left to the lecturer in the choice of his subject. The Harveian oration, on the other hand, is generally anything but a success, because the "orator" is to a considerable extent tied down. The "orator" of this year, Dr. Pavy, in his "oration" on October 18, ventured to give a slight sketch of the germ-theory of disease, but, probably from want of a thorough acquaintance with it, failed to make his subject interesting; and such failure is but too common.

Dr. Alfred Hill, in his address on taking the chair as President of the Society of Medical Officers of Health, defended the water-carriage system of sewage, which, though in almost universal use in this country, has recently been attacked on various accounts. He said that the sewage of a town with water-closets was but little more offensive than that of a town which had no water-closets, and that with the latter matter was carried instantly and readily by gravitation to its proper destination, which was, of course, the land. The sewage of some of the districts of Birmingham is used for irrigating land, and a considerable sum was realized last year by the sale of stock and produce. Dr. Hill thought that the difficulty of obtaining land suitable for irrigation had been greatly exaggerated, and stated that the amount of land which experience at Birmingham had shown to be sufficient was one acre to every five hundred persons. London is said to be on the eve of a large expenditure to cover the cost of precipitating and deodorizing its sewage, which until the other day was discharged into the Thames in the crude state: even now very little is precipitated. Dr. Hill calculated that, if the sewage of London were utilized on sewage-farms, it would raise vegetables, milk, and meat worth two hundred thousand pounds a year. The necessary works and farms would, however, probably cost an appalling sum, since at least eight thousand acres of arable land, well drained to six feet, would be required.

Professor Hamilton, of Aberdeen, showed at the last meeting of the Pathological Society of London a series of sections of the brain which are probably the most beautiful that have ever been seen in this country. During the series of manipulations to which they are subjected, the sections are stretched so that they are a third to a half larger than natural. He showed sections through the whole, both in the transverse and in the horizontal direction: one made through the corpus callosum had, when viewed in a transparency, almost the distinctness and definition of a diagram. It would be tedious to recount the very elaborate method followed to obtain these beautiful preparations, but the two chief peculiarities about it are that the brain is hardened by being continuously injected (through the vessels) for a week, and that the section, which is cut in a large microtome, is allowed to fall into water, and then caught upon the surface of a glass plate covered with a layer of gelatin; a second layer of gelatin is run over the specimen, and all subsequent manipulations are applied to the section encased in this double layer of gelatin.

The contested elections for the five seats on the General Medical Council continue to excite a great deal of attention, and a whole series of "organizations" and committees, each with its chairman or president, execu-

tive committee, and, as a rule, a treasurer, are at work. There is a great sameness about the addresses, and it is quite impossible to forecast the result.

Mr. Victor Horsley has operated upon another patient with tumor cerebri: he excised a very large tumor, and the patient, who was under the care of Dr. Ferrier, got over the operation well. I hear that in one of his earlier cases the epileptiform fits are beginning to return.

At the meeting of the Ophthalmological Society on October 21, Messrs. Edmunds and Lawford contributed a concluding paper on the mode of production of optic neuritis in head-injuries. Their general conclusion is that when meningitis occurs at the base there will always be optic neuritis, but that when there is no basic meningitis there will be no optic neuritis. DAWSON WILLIAMS.

LONDON, October 23, 1886.

NOTES FROM PARIS SOCIETIES.

THE Influence of Nerves on the Secretion of Lymph.—At a recent meeting of the Academy of Sciences, M. Serge Lewachen stated that by means of an aspirator, which insures a free and constant flow of lymph surrounding the lymphatics of the saphena vein, he can now prove that, if under any nervous influence a certain modification in the circulation of the blood ensues, it always determines a variation in the secretion of lymph. On stimulating the vaso-motor nerves (constrictors and dilators), modification in the quantity of the lymph results. These modifications are identical, whatever nerves are stimulated. M. Lewachen considers these changes to be in direct connection with the circulation in the corresponding limb.

In a second communication read before the same institution, M. Lewachen stated that he had sought to ascertain if similar modifications in the circulatory system, occurring under the influence of the vaso-dilator and vaso-constrictor nerves, determine variations in lymphatic secretion of the same intensity or a different intensity. This investigator made experiments on the tongue. It is known that vaso-constrictor fibres of the hypoglossus nerve and vaso-dilator fibres of the lingual nerve are sent to the tongue. On stimulating either the hypoglossus or the lingual nerve, separate action of each variety of the vaso-motor fibres can be produced. Except the lymphatic vessel under observation, M. Lewachen severed all collateral vessels on the side of the tongue on which he was experimenting and ligated the lymphatic vessels. The following results were obtained. Section of the hypoglossus nerve was followed by an increased quantity of lymphatic secretion; stimulating the peripheral extremity resulted in a decrease of the secretion of lymph. Section of the lingual nerve is not constant in its effect. Stimulating this nerve greatly increased the secretion of lymph: this increase continues after section of the hypoglossus. If electrical stimulation be increased until lymphatic secretion reaches its maximum, section of the hypoglossus is without effect. The lymphatic secretion is more abundant when the lingual nerve is submitted to a maximum of electric stimulation than it is when the hypoglossus nerve is cut. Thus, the action of the vaso-dilators is more powerful: this is owing to the fact that the vaso-dilators have a more powerful action on the circulation of the blood, and also have a direct action on the walls of the vessels, which perhaps tends to modify their permeability.

Division of Cellular Elements in Tumors.—At a recent meeting of the Academy of Sciences, M. Marey read a note from M. Cornil relating to a new method of segmentation he has recently observed in the epithelial cells of epithelioma. In sections colored by saffronine hæmatoxylin, a large number of nuclei are seen in which the chromatic filament is highly colored and represents the form of a star, with seed-like bodies of chromatic properties. Some of these nuclei are colossal and present a central disk, and the filaments divide later on: it is the beginning of kariokinesis. When the filament of the nucleus is colored, it presents a trilobular aspect: this is the first change attending the phenomenon of division, which results in the formation of three new cells. In the second period a further change takes place, and three nuclear disks are seen in a single nucleus. Finally, complete evolution is achieved, and the cell divides into three new cells.

New Instruments.—At a recent meeting of the Paris Biological Society, M. Malassez, of the College of France, presented a series of instruments consisting of a calorimeter, a glass cylindrical receptacle for spectroscopic examinations, a warm stage, and a heating-plate for warming preparations. M. Malassez drew attention to the advantages of lighting by means of naphtha-carbol, which he considers should be more frequently used in laboratories, on account of the light being white and emitting only a slight amount of heat, yet burning steadily and never flickering.

At the same meeting, M. Boucheron made a statement concerning his investigations on microbe in chalazion. He cultivated and reproduced with them experimental tumors. In weak animals he has sometimes observed superficial or deep lesions of the kidneys.

Papilloma.—At a meeting of the Biological Society, M. Blanchard presented a lizard attacked with a papilloma on the back: the tumor was probably of acarian origin. At the same meeting M. Blanchard described

tænia nana, a parasite seldom met with. Leuckhart and all other writers have made an incorrect statement in declaring that the head is invaginated. Such is not the case, as the head is evaginated; but a few muscular fibres which extend behind the rostrum can during contraction draw it backward, and so form a cavity, but this cavity is not the head of the animal: the head is contained in it. The rostrum itself cannot be inverted; this is impossible, and is a general law equally true of all other worms.

New Observations on the Classification of Alkaloids.—At a recent meeting of the Biological Society, M. Oechsner de Coninck read a paper on oxidized artificial alkaloids. He said that it was still necessary to give the preference to the physical character of alkaloids in order to classify them. With many writers oxidized alkaloids are said to be unalterable, which is an error that should be corrected: there exist volatile oxidized alkaloids. It is probable that alkaloids will be arranged according to the connection they bear to alkaloids of the pyridic and quinoleic series, or, in other words, according as they constitute pyridic or quinoleic hydrates, or oxypyridic or oxyquinoleic hydrates, or complex molecules with a hydrogenized dipyridic or diquinoleic centre, or with a mixed pyridic or quinoleic centre also hydrogenized.

P.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

A MEETING of the Philadelphia Academy of Surgery was held November 1, 1886, Vice-President Dr. S. W. Gross in the chair.

Dr. C. B. Nancrede read the following report of a

GUNSHOT-WOUND OF THE ABDOMEN.

On July 24 I was sent for to see a boy, brought into the hospital about two o'clock with a pistol-ball wound (twenty-two calibre) of the abdomen. The boy was about 15 years of age. The wound of entrance was two inches above the umbilicus, and one inch to the left of the median line. There was no hemorrhage from the external wound, and the boy complained little of pain. The symptoms of shock were very slight. Three-fourths of an hour after admission he vomited, but the vomited matters were free from blood. Half an hour later he again vomited, bringing up some blood and some coffee-ground particles. Between four and seven o'clock he vomited pure blood several times. In all he vomited about twenty ounces of blood. An ice-bag was applied to the abdomen, and three drops of liquor ferri subsulphatis were given by the mouth by the resident physician. Nutritious enemata were given. He continued to spit blood until I saw him, at 10.30 P.M.

I then found no particular abdominal tenderness, and all evidences of shock had passed away. Operation was decided upon. I first introduced a probe into the track of the wound, in order to be sure that the peritoneal cavity had been opened. Finding such to be the case, I made an incision in the median line. I first found what appeared to be a contused wound on the anterior surface of the stomach. Pressure on the stomach, however, caused no escape of liquid or gas, although the viscus was distended. A director was placed in the wound, and after a little manipulation it entered the stomach and blood began to flow. The opening was at once sutured with the ordinary Lembert suture. Examining further, a large ragged wound was found in the anterior wall of the duodenum. An opening was also found in the posterior wall of the stomach. This, while not so large as the wound in the duodenum, was larger than the wound of entrance in the stomach. On the posterior surface of the duodenum another and much larger and more ragged opening was found. These were likewise closed with sutures, and the remainder of the small intestine was examined without finding any more wounds. The ball was not found. The wounds were so thoroughly closed that there was no escape of blood or other matters during the manipulation of the organs. The toilet of the peritoneum was performed with great care, and the external wound was closed, a drainage-tube being inserted in the track of the ball.

The following day I found the boy moving freely in bed, with no complaint of pain. There was not the slightest tension, and no tenderness. The following day the condition continued the same, and the abdomen was actually scaphoid. In the evening, about forty-eight hours after operation, the temperature began to rise, but still there was no tenderness. He became slightly delirious. The temperature steadily rose until it reached 108.4°. Convulsions appeared, and continued to recur. There was, however, no tenderness, no distention of the abdomen, and no discomfort complained of. The patient died at half-past twelve o'clock on July 27. I had charge of the case only during the first thirty-six hours.

I am at a loss to decide what the boy died of. In speaking with a prominent nervous specialist in reference to this case, he could only suggest that the convulsions were reflex, probably due to irritation of the solar plexus, and that the temperature was due to a nervous disturbance. There were none of the rational signs of peritonitis, and I concluded that this was not the cause of death; but, since

a post-mortem examination was refused, this must remain a subject of conjecture.

Dr. C. W. Dulles: In this case the high temperature would raise a suspicion that there was involvement of the heat-centre in the brain. The occurrence of convulsions would also point to disturbance of the brain. A blood-clot swept into the cerebral vessels and causing embolism would account for the symptoms presented. One word with reference to the complete absence of peritonitis in this case. I have seen cases in which almost all the signs of peritonitis were absent, and yet the autopsy has shown peritonitis to be present. It is a well-recognized fact that rise of temperature and frequency of pulse may be absent in peritonitis. I have also seen the abdomen perfectly flaccid. It is, therefore, not perfectly clear that peritonitis was absent in this instance. At the same time, taking the absence of these symptoms with the history of the case, there is reason to believe that there was cerebral lesion.

Dr. S. W. Gross: In the *New York Medical Record* of October 16, Dr. Charles A. Jersey reports a case of pistol-shot wound of the abdomen in which he sewed up four wounds of the intestine and two of the mesentery. The patient died of peritonitis. The wounds in the intestine had healed, but those in the mesentery had sloughed. The fatal result was due apparently to the fact that the mesentery had not been excised before the application of the sutures. An important point to be remembered is that, if the mesentery be damaged, the damaged portion should be excised.

Dr. C. B. Nancrede: In seeking for an explanation of the cause of death in this instance, the embolic theory suggested itself to me. I believe that the high temperature was due to nervous disturbance. I am perfectly aware of the fact that peritonitis may be present without any of the rational signs being found, having met with such cases in my own practice, and in some of these cases the temperature may be almost subnormal. After an injury of this kind, I think, however, if general peritonitis appeared, it would show some symptoms of its presence.

An interesting point in this case was the complete closure of the wound of entrance in the stomach, through which no blood or other matters escaped until it had been opened with a probe. It is probable in such cases, where there is only one clean-cut wound of the stomach, that the ball is passed by the bowel and the patient recovers.*

ROUND-CELLED SARCOMA OF NASAL CAVITY.

Dr. De Forest Willard reported a case and exhibited microscopic specimens of sarcoma of the nose in a woman.

The patient (from whose tumor the various sections seen under the microscopes upon the table were taken) was a woman 32 years of age, without discoverable hereditary tendencies. One year before coming under my care she began to complain of a sensation of fulness in the left nostril, which soon increased and became painful. In six months she was unable to breathe through that side, and for the past two months the pain has been steadily increasing, until it is now extreme. The ala and the nasal and superior maxillary boundaries of the nose are beginning to bulge markedly. The left nasal cavity is entirely blockaded. No diagnosis of the trouble has heretofore been made, and treatment has been but palliative. Immediate operation recommended, and sarcomatous nature of the growth distinctly stated.

During the four days' delay necessitated by domestic arrangements most intense meningeal pains commenced, indicating pressure from below upon the brain. No time was lost, and on the following day an incision was made from the inner line of the orbit into the nasal orifice, laying the ala over towards the median line. This incision was subsequently extended to the angle of the mouth, and the septum narium divided so as to permit the soft tissues to lie well out of the way. As the growth had invaded the roof of the mouth, the maxilla was cut through a little to the right of the median line, so as to permit the removal of the nasal septum, which, although bounding the growth, was itself implicated. The left section of maxilla was also made with saw between the canine and first bicuspid, and extended back through hard and also soft palate, as the latter was found to be nodulated and infiltrated. Through this opening were removed by forceps the turbinate, vomer, and portions of left maxillary, nasal, ethmoid, and sphenoid, until apparently healthy tissue was reached on all sides. In picking away the ethmoidal cells, it was found that the extreme boundary of the neoplasm had just involved the floor of the skull, and a minute portion of the thin plate, being infiltrated, was brought away, disclosing the dura mater. The hemorrhage during the entire operation did not exceed three ounces, although the removal had been so extensive. The saw and forceps were alone used after the primary incision.

The patient rallied well, and the severe headache was greatly relieved. On the following day it returned; the temperature rose rapidly to 105°, pulse 160. There were slight convulsions, followed by stupor, delirium, and death on the fifth day, from meningitis, which had undoubtedly commenced on the day prior to the operation. No post-mortem was permitted.

The specimens were thoroughly examined by sections and with various stainings by Dr. J. P. Crozier Griffith, who reported that the

* Since this discussion was held, Dr. Gross has suggested to the author what seems highly probable, that the cause of death was septic mortification, *i e*, septicæmia, not due to peritonitis, but to the absorption of ptomaïnes from decomposing fluids.

growth was a small round-celled sarcoma, which had infiltrated the surrounding parts to so great a degree that it was impossible to decide whether bone or soft tissues had been first involved. Even the bundles of muscular fibres removed from the cheek were almost obliterated by the cellular infiltration, and in many places the small round cells were found in the inter-fascicular spaces. The mucous membrane of the roof of the mouth was unaffected, while the submucous connective tissue in some preparations was crowded with sarcomatous cells. The palatal process of the superior maxilla was greatly thickened and very porous. The bone-substance was largely destroyed and penetrated by irregular-shaped cavities, which contained round cells and many myeloplaxes. None of these latter were found in any other portion of the growth.

Several of the preparations exhibited beautiful specimens of "obliterative endocarditis," in some instances almost occluding the vessel.

CASES ILLUSTRATING THE RESULTS OF ANTISEPTIC SURGERY.

Dr. Thomas G. Morton presented a number of cases from the Pennsylvania Hospital which illustrated results obtained by perfect antisepsis.

Case I. Compound Depressed Fracture of the Skull.—The patient, a man, 19 years of age, was admitted to the hospital October 7, having been struck on the head with a shifting-apparatus while on shipboard. On admission he presented a small laceration in the fronto-parietal region, with a slight depression. No brain-symptoms were present. An incision was made into the scalp in order to determine whether or not there was greater depression than appeared externally. A marked depression was found, and the trephine was applied. The whole thickness of the bone was depressed. The portion removed was equal in size to two quarters of a dollar. A catgut drain was introduced to the bottom of the wound, and an antiseptic dressing applied. On the fifth day the patient was out of bed. He had no untoward symptoms, and on October 23 the first and only dressing was removed. The catgut drain had disappeared, as well as the catgut sutures, with the exception of those portions outside of the skin. At the moment of trephining the temperature was 100°, but it never went above 99° after the operation.

Case II.—A man, aged 20 years, was admitted August 30, with a crush of the foot, for which a Pirogoff amputation was performed. The flap sloughed, requiring re-amputation, which was performed October 2, under full antisepsis. I made a Teale amputation in the upper third of the leg. Drainage was accomplished by half a dozen No. 3 catgut threads. On October 23 the wound was dressed for the first and last time. The dressings did not present the slightest moisture, and, as in the previous case, the catgut had disappeared.

Case III.—A boy, aged 13 years, came in with a crush of the anterior part of the foot, requiring a Hey amputation. He was admitted October 1, and discharged October 23. There was but one dressing, and the union was complete.

Case IV.—This is an interesting case which I have had under my own care, the only one of the kind I have ever seen. It is a case of rupture of the long head of the biceps. While shovelling dirt out of a ten-foot hole, this man felt something tear in the upper part of the right arm. He at once lost power in the limb. The arm was painful, and a lump the size of a goose-egg appeared above the elbow. On striking it, this lump became hard. The slightest irritation produced a condition of painful muscular spasm, which soon relaxed.

The operation was performed as follows: Two incisions were made, one over the muscle-mass and the other over the median portion of the deltoid. The tendon was found coiled up at the upper portion of the muscle-mass. It was pushed with forceps subcutaneously into the upper wound, and its frayed portion cut off. The tendon was then attached deep in the deltoid by fourteen catgut sutures, and about two dozen were passed through the muscle and tendon. The patient was admitted on the 7th, and the dressing removed on the 23d. There was firm union, and the man can now flex his arm very well.

Case V.—This is a case of entire division of the biceps muscle and the brachial artery by a knife. The artery was tied with catgut at both ends, and the muscle sutured with the same material. The first dressing was removed at the end of two weeks. Where the drain had emerged there was a small opening, which soon closed. The second dressing took place two weeks later, when the wound was found entirely healed.

Dr. J. William White: In reference to the use of catgut drains in trephining cases, I recall a case that I trephined one or two years ago, in which I regretted their use very much. The trouble was probably due to imperfect catgut. In this case there was some oozing of blood, and the catgut became matted together. On account of the oozing, it was found necessary to redress the wound in thirty hours. The catgut was found hardened and incapable of acting as a drain. The drain seemed to be really a source of irritation. The catgut was removed, and the patient made an excellent recovery. In other situations this complication might not be so important, but in the case of trephining it exposes the patient to serious danger.

Dr. C. B. Nancrede: With reference to catgut drains, I can bear out what Dr. White has stated. I wish distinctly not to make

any claim to priority, but simply to state that I believe that I was the first in this city to prepare catgut for use in the thorough Lister operation. I believe that catgut drains are often inefficient. I have employed the method of the originator, Cheyne: taking some twenty strands, doubling them in the middle, and securing it to the bottom of the wound. Three or four strands are then brought out between every two sutures, taking care to keep them close together. In some cases this acts admirably, while in other cases, although the strands are arranged in an exactly similar manner, the catgut has not acted as a drain. The reason for this difference I do not know.

Dr. J. H. Packard: I have noticed that catgut differs much in quality. The best is perfectly smooth; but there is some which is rough and ragged when examined with the microscope. This is weaker than the perfectly smooth, round catgut. It may be that this flocculent matter impairs the efficiency of the small capillary tubes formed by the interstices between the strands.

Dr. J. Ewing Mears: At the St. Mary's Hospital, in wounds of the scalp and of the cranium we use horse-hair for drainage. This serves an excellent purpose. Sometimes we employ horse-hair in tubes, as advised by Cheyne, drawing out one hair at a time.

I have listened to the remarks of Dr. Morton, and examined the cases he has presented, with mingled feelings of gratification and regret. I am gratified that he brings us such beautiful illustrations of methods which have been in use for some time, and shows what can be accomplished by a thorough practice of antiseptic methods. I regret that the surgeons of the Pennsylvania Hospital did not sooner throw the great influence of that venerable institution in favor of the use of antiseptic methods, and thus help those who have been fighting the battle for them for a long time. The results at this institution have been most perfect; but if they had practised antiseptic surgery some years ago their results would have been as perfect as they are to-day.

In 1876 I showed Mr. Lister the result in a case of compound fracture into the elbow-joint. This was treated on the plan advocated by him at that period with the carbolized putty and oil. The dressing was removed on the fourteenth day, when the wound was found to be healed and there was perfect motion of the joint. Mr. Lister said that that was one among the few cases of antiseptic surgery that he had seen practised in this country.

Dr. J. William White: I should like to ask a question with regard to the desirability of attempting to cure a case with one dressing. This is, of course, less troublesome to the surgeon and to the patient. I would ask if it is desirable to wait for the appearance of general symptoms before changing the dressing. At the end of twenty-four hours the oozing has usually ceased. If you do not make it a rule to examine the dressings within the first forty-eight hours, the first indication may be an elevation of temperature or some evidence about the wound that things are not going right. The mischief may then be irremediable.

Dr. William Hunt: There is one class of cases which requires frequent dressing, and that is where there is a compound fracture. There the temperature-chart shows nothing as to the position of the bone. The bones may be in proper position to-day and within twenty-four hours be displaced.

Dr. J. M. Barton: I think that Dr. White's point is well taken. I make it a rule to change the dressing in twenty-four hours. I have the fresh gauze ready, and almost instantly remove the old and apply the fresh. Occasionally I examine the dressing six or seven days later.

Dr. William Hunt: I think that there is too much routine in reference to the use of drainage. All cases do not require it. There are many cases in which I am confident that adhesion would have taken place without the use of drainage.

Dr. Chas. W. Dulles: I agree with Dr. Hunt that there are many cases that do not require drainage, and perhaps the success of catgut for this purpose is because it does not act as a drain. In many cases the amount of discharge which they bring from a wound is very small. The catgut occupies parts that otherwise would be cavities. They fill these parts with a clean material, which may become organized, or be gradually carried away by absorption and be replaced by normal tissue.

I would also refer to the unnecessary fear of blood-clots. They are of no consequence, provided the wound is absolutely clean. I am convinced of the value of aseptic surgery. Many of the minutiæ of so-called antiseptic surgery are mere puerilities, and are only useful as they secure cleanliness on the part of the surgeon and his assistants. I have seen many wounds heal under perfectly clean water-dressings and with the dry-dressing of Mr. Gamgee. I think that if these methods could be carried out scientifically the results would be as good as with antiseptic surgery.

Dr. J. William White: I think, in the face of the statistics which we have at this day, that no rational claim can be made which will place on the same basis the results of surgical methods which depend upon cleanliness alone and those which carry out thoroughly and in all their details antiseptic methods.

Dr. S. W. Gross: The greatest triumph of aseptic surgery has been shown within the past few months in a paper read by Mr. Victor Horsley at the recent meeting of the British Medical Association, and published in the

British Medical Journal for October 9. He has made many experiments as to the localization of the functions of the brain. In the paper referred to, Mr. Horsley reports one case in which he removed a tubercular tumor of the brain involving the motor area. In four days the wound had healed. In two cases of epilepsy he removed the cicatricial tissue along with a portion of the brain-substance. In one of these cases the wound was entirely healed at the end of a week, and in the other, three-fourths of the wound was healed on the seventh day. In the last case he removed a tumor from the brain which measured three inches by two, by two and one-half inches, and weighed four and one-fourth ounces. The wound was healed in four days. No better results than these can be shown. Mr. Horsley carries out all the old Listerian details with the spray, gauze, etc.

It is interesting to note that he makes no small incision either in the soft parts or in the skull. The trephine which he uses is two inches in diameter. The incision in the dura mater is one-fourth of an inch inside of the edge of the opening in the bone. This is brought together with stitches. The external wound is closed with sutures, and a small drainage-tube inserted. At the end of twenty-four hours he removes the tube. He says that when the brain-tissue is cut away there is a tendency for the brain-substance to rise into the wound and evert itself. There is a disposition to hernia cerebri. The discharge, which is the result of the irritation produced by the antiseptic, will have stopped at the end of twenty-four hours. At the end of this time he removes the tube, and keeps a certain amount of discharge within the skull in order to give support to the brain and prevent the tendency to protrusion. This is the most remarkable series of cases that I have seen reported.

I think that when Dr. Morton has used the catgut drainage in a larger number of cases, the time will come when he will throw it to one side. It will do for small wounds, because there is nothing to be drained after twenty-four hours. I am in the habit of practising aseptic surgery, and have used catgut as was recommended by Cheyne, and I have used bone tubes, but I have gone back to the rubber tubes, and now use nothing else. I do not care to change my dressings at the end of thirty-six or forty-eight hours. I am guided as to the time to renew the dressing by the temperature-chart. If everything does well, I change the dressings at the end of seven or eight days. After a few days the drainage-tube may be removed, for its track will be lined by granulations which will keep it open sufficiently long to allow the escape of any fluids. Drainage-tubes are often kept in long after the necessity for them has passed away.

Dr. T. G. Morton: High temperature does not always furnish an indication for renewing the dressing. In a recent case the temperature ran up to 103°, but I did not remove the dressing. A careful examination of the patient revealed a diphtheritic patch on one tonsil. It seems to me that it is better to disturb the dressing as little as possible. I should not remove the dressing unless there was some indication for it or I knew that union had taken place.

Dr. Charles W. Dulles presented

SPECIMENS FROM A CASE OF OÖPHORECTOMY.

These ovaries were removed from a case in which I did Tait's operation ten days ago. There was union by first intention on the sixth day. The operation was unintentionally done within three days of the close of the menstrual flow. Menstruation returned on the fourth day after operation. The day after the operation the temperature went up to 100.6°, but since then it has not been above 100°. The patient was 26 years of age, and the operation was done on account of the mental condition, which I believed to verge on insanity. Both ovaries are in a state of cystic degeneration. The cysts were more distinct at the time of the operation than they are now.

On the motion of Dr. Mears, these ovaries were referred to a committee for examination. The committee consists of Drs. Dulles, Mears, and Simes.

Adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, OCTOBER 7, 1886.

The President, B. F. BAER, M.D., in the chair.

RUPTURED FALLOPIAN PREGNANCY, LEFT SIDE.

DR. JOSEPH PRICE exhibited the ovary and distended tube, which had burst spontaneously. No fœtus was discovered; a very free hemorrhage into the peritoneal cavity had occurred. In the vast majority of cases the rupture is fatal. The cause of death is invariably hemorrhage.

Dr. PRICE also exhibited specimens from a case of

DOUBLE PYOSALPINX WITH CYST OF THE RIGHT BROAD LIGAMENT AND ABSCESS OF THE OVARY OF THE SAME SIDE.

The specimen consisted of both Fallopian tubes and ovaries, and was a good example of pyosalpinx, both tubes being closed at the ends and distended with pus. The right tube was long and very much distended, and with a large abscess of the ovary, and a cyst of the broad ligament as large as a base-ball occupied the whole of the right side of the pelvic cavity, where the entire mass was firmly bound down and gave rise to great suffering.

The diagnosis in this class of cases is

made or it is not made. He is quite sure Mr. Tait, before proceeding to an operation, is fairly certain of his diagnosis, and this generally presents but little difficulty. It is true that he operates early, as soon as he recognizes dangerous trouble. Dr. Price feels certain that delay with us is accountable for the large death-rate. Dr. Mundé says of Mr. Tait, "Now his wonderful dexterity and tactile sense come into play; for with these fingers he at once makes the diagnosis, which he appears to pride himself on not attempting to make with accuracy in those cases demanding removal of the uterine appendages, the so-called 'Tait's operation,' except through the abdominal incision."

While at Birmingham, recently, Dr. Price visited regularly Mr. Tait's large public clinic, and watched carefully his rapid examination. Dr. Price cited one case to illustrate the fact that Mr. Tait made his diagnosis through the vagina. After passing a number of cases, displacements, etc., which he did not think of sufficient importance to ask us to examine, he came to one and kindly asked us to examine and express an opinion. Dr. Price examined, and found the physical characteristics of pus. Mr. Tait's reply was, "Quite right." The patient was at once sent to Spark Hill for operation. One tube was found full of pus, the other partially filled, and the ovaries cystic. This case illustrates that Tait does not guess at conditions and resort to abdominal section for diagnostic purposes. A world of mischief has already come of such statements. Of course there are exceptional cases demanding exploratory incision. Tait says, "Save when the seat of such organic disease as will explain genuine suffering, the uterine appendages ought not to be removed," and that "those who attribute all the pelvic aches and ails of women to the ovaries and tubes, and rush in to remove them, are dangerous people."

Dr. LONGAKER considered the first case one of tubal pregnancy. Recurring attacks of peritonitis should direct attention to the probability of pyosalpinx. The condition should be easily recognized, but it is sometimes overlooked.

Dr. HOWARD A. KELLY remarked that, in view of the increasing number of cases of hæmatosalpinx which we were now meeting, it was of the utmost importance that all those which came under our immediate notice should receive a more rigid examination, and elaborate attention should be directed to the clinical history. He believed positive diagnostic signs would be discovered which will make our interference more a matter of scientific certainty.

Dr. Kelly was not speaking of those cases of a minor degree of tubal apoplexy or hemorrhage symptomatic of a grave dyscrasia, but of those in which, owing either to a closure of an outlet, or to disease of the mucous membrane of the tubes, or to grave local circulatory disturbance, a mass collected, forming a sausage-like tumor, producing various symptoms, some of which are common to pyosalpinx. There is always great local tenderness, and often there are masses of exudate embedding and obscuring the original tumor, and, in cases of rupture, often a peritonitis as rapidly fatal as in pus cases.

The suspicion that a tubal pregnancy lies at the bottom of the explanation in all these cases is negatived by the fact that a majority of the cases are hæmatosalpinx of both tubes.

A very important symptom, which he learned was present in Dr. Price's case, was also prominent in his own case: that is, a stillicidium of bloody, grumous material per uterus and vaginam, which is regarded by the patient as a prolonged menstrual period. This undoubtedly flows from the tube, and is altogether analogous to the free purulent discharge from the tubes of pyosalpinx which he had seen. He intends in the next case of this kind to catheterize the tube and dilate, and endeavor to relieve his case of hæmatosalpinx or pyosalpinx in this way if the discharge exist in sufficient quantity to lead him to suspect a patulous uterine orifice.

Cases of hæmatosalpinx resulting in rupture and death have been reported: one is figured by Winckel.

There are several facts in connection with the life-history of pyosalpinx which he would like to emphasize. In the first place, he had seen no case which was not the product of a gonorrhœal infection; and, while not prepared to deny the possibility of a purulent change in the contents of a hydrosalpinx, for which Bandl contends, these cases, so ably worked up by Dr. Price, and his own observations elsewhere, all point to *gonorrhœa*.

Again: *these cases, with a history of such acute onset*, constant agonizing pain and constant high temperature, and often typhoid condition, are the advance stages of a florid gonorrhœa, and are found almost exclusively among the unmarried, and result from contact with a similarly active gonorrhœa in the male. They form a picture utterly different from that developing from the exposure of a wife to the discharges of a husband who has been told that a trifling gleety discharge amounts to nothing, or who has long appeared well, only noticing the discharge after occasional debauches or unusual sexual indulgence. *Here the disease assumes the insidious sneaking type*, commencing with little periodical pains scarcely noticed at first, a slight excess of menstrual flow with more pain after, and so on for months, until perhaps an abortion or a pregnancy completed seems to open up channels for a more serious and general infection. He had had typical cases of this in his own practice. It will be often noticeable here that, in view of the much greater suffering experienced after the puerperal period,

the patient will forget what has gone before, and blame her subsequent trouble on the mismanagement of the doctor.

The extreme importance of this whole question, second to none in the whole range of gynæcological investigation, suggests to the mind many pertinent inquiries. What parts of the female genital tract are the favorite seats of the disease? In what order are the structures attacked? May it linger long in one part, and then, under some change of condition, attack another part? What is the resisting power of the virus to our various therapeutic agents?

The third question he believed he could answer satisfactorily. In addition to the well-known cases in which the disease lingers indefinitely in the urethral tubules and the vulvo-vaginal glands, *he believed that in many of our cases of pyosalpinx the disease has already lingered for a long time in the uterine mucosa, and has shown itself in the form of a uterine catarrh.* Since formulating this doctrine for himself, it had necessarily carried him back to the treatment of many of his cases by topical intra-uterine remedies, a form of treatment which he had some time since abandoned as irrational.

A patient is now coming to his office from whose pelvis he literally quarried out a large stinking tubo-ovarian pus-sac. The left tube and ovary were unaffected, and he left them. She has a free purulent discharge from the uterus, for which the only rational treatment is active local measures.

It is important to recognize the fact that, apart from a slight irritation of the outlets of the glands at the vulvar orifice, there may be no other signs of gonorrhœal disease than such discharge as issues from the os uteri. The vagina may be perfectly sound. Braun and Schwartz lay especial emphasis on the fact that the flat epithelium of the vagina has great powers of resistance against the poison, while delicate epithelial structures, particularly the ciliated, are its favorite resting-places.

We will apply our remedies with some success if we bear in mind the fact that the disease does not merely lie on the surface, waiting to be wiped off to effect a cure, nor does it merely penetrate the tubular glands; but it invades the interior of the individual cells and attacks the nuclei. It penetrates not only the strata of connective tissue below, but also blood-vessels and lymph-spaces, and forms thrombi. Relapses, then, even after the most energetic treatment, need not surprise us.

We find here, as in many other points, our forefathers did wiser than they knew: their therapeutic resources reached far beyond their knowledge of etiology. No wonder they used the most powerful acids, and loved to leave a stick of solid nitrate of silver in the uterus to cure this most obstinate catarrh. When he cannot succeed in catheterizing some of these cases, he knows of no other way in which a perceptible deposit of pus, once formed in a tube, can be removed but by the radical operation. And let there be no delay here. Cases have been lost simply from the secondary consequences of carrying around this bag of pus in the abdomen. Dr. Veit alone lost two cases from brown atrophy of the heart.

Dr. M. PRICE remarked that the good results in his brother's operation were due to free irrigation: from three to five gallons of warm water were used to cleanse the peritoneal cavity, and to stream through it for ten or fifteen minutes.

Dr. BAER made some remarks upon the value of intra-uterine medication. Although high authorities had denounced it as unnecessary and dangerous, he had continued to use it: he has never given it up, as he has always found cases where it was needed. The method has been productive of good results in his hands, and he never expects to give it up. It will not cure pyosalpinx, but it may prevent it. It will be ludicrous to see the ultra-scientific return to intra-uterine medication after the denunciation to which it has been subjected. Dr. Baer preferred the injection of tincture of iodine, carbolic acid, nitric acid, or whatever application may be preferred, say about twenty minims by means of a hard-rubber syringe, to any of the cotton-wrapped or other form of application. No case of inflammation has thus far followed this method of treatment in his hands, and he has less uterine colic than with the applicator,—perhaps because less force is required. No tenaculum or counter-pressure is necessary.

Dr. J. PRICE, in closing the discussion, remarked that in the first case there had been a missed period, and two or three weeks later a flow of blood commenced and was continuous for weeks, with tenderness of the abdomen. By the microscope only can an exact diagnosis be made between hæmatosalpinx and tubal pregnancy, and he had had no opportunity of making an accurate one. Rupture may occur early in tubal pregnancy.

An unhealthy condition of the endometrium is very rare. The abortive treatment of gonorrhœa, as applied to the male urethra, has resulted in orchitis and stricture. The case of pyosalpinx was operated upon four weeks after an abortion.

Dr. DRYSDALE, in view of recent strictures upon intra-uterine medication, would like to mention a case seen by him under Mr. Tait's treatment in 1883. The condition was endometritis, and Mr. Tait etherized the patient, dilated the uterus, and applied the Paquelin thermo-cautery thoroughly to the endometrium.

Dr. B. F. BAER presented the specimen and related the following history of

A CASE OF FIBRO-SARCOMATOUS TUMOR OF THE OVARY.

Mrs. ——, aged 36 years, married; two children, youngest fifteen years of age. About July, 1885, she first noticed that the lower portion of her abdomen was increasing in size, especially in the left iliac region, and she was troubled greatly with flatulent dyspepsia. She had suffered for many months before with pain in the left iliac region, and on November 29 she was seized with what she characterized as terrible pains in that region. She was compelled to take to her bed, and her physician said she had pelvic peritonitis. She remained in bed three weeks, when she became able to be up, still suffering considerable pain, however, with diarrhœa and an occasional discharge of blood from the rectum. She now noticed a hardness in the lower left iliac region. This continued to increase in size, while she grew weaker and began to lose flesh. At this time she passed into the hands of another physician, who ordered her back to bed and blistered the surface of the abdomen. She remained in bed four weeks, but the growth failed to diminish in size; on the contrary, it continued to increase. On February 10 she was able to get up, and began to feel stronger, but suffered from excessive tympany, together with nausea, loss of appetite, and great pressure upon the rectum and bladder. She also suffered from severe dyspnœa.

On March 20 she was suddenly seized with cramp-like pains in the region of the tumor. These continued for a few days, with almost entire absence of sleep, and with continuous nausea. The pain gradually subsided, but she was losing flesh and strength. She had another attack of pain, with such dyspnœa as to make her recovery a matter of doubt. Ten days later she first consulted me.

On examination, I found the abdomen greatly distended and tympanitic, except in the left hypogastric region, which was dull on percussion. Palpation revealed an irregular, lobulated mass, apparently having pelvic connections. The uterus occupied the right anterior portion of the pelvis, crowded over by the mass in the left pelvic region. This mass was hard and firm and nodulated, extended into the hypogastric region, and was apparently closely connected with the uterus, as well as with the other organs of the pelvis.

The previous history of the case, together with the physical signs now present, led me to suspect the presence of pus, possibly suppuration in a thick-walled ovarian cyst. The uterus measured two and a half inches in depth. Its connection with the tumor did not seem more than ligamentous, and the apparent rapid development weighed against fibroid tumor of that organ.

The indications were plain. The patient entered my private hospital April 29. Ether was administered, and an exploratory incision was made. This revealed a nodulated mass having the color and appearance of a thick-walled ovarian cyst; but it seemed to be solid throughout, and was firmly fixed in the pelvis. Its size could not be reduced, and the incision was increased to six inches, and the tumor separated from its adhesions and lifted from its nest. I was much gratified to find that it had a very small pedicle, which was tied, and the tumor was removed.

The patient bore the operation badly, and it was thought that she would succumb on the table. It was hours before the pulse could be felt at the wrist; but she rallied, and the next morning she seemed to be doing quite well. A free discharge of bloody serum had taken place through the drainage-tube. After alternate sinkings and rallyings, she died on the evening of the second day, from shock, from which she had not entirely recovered since the operation. There was not the slightest evidence of inflammatory action. The discharge from the drainage-tube had ceased, and the wound was healing nicely.

This case is interesting on account of the character of the tumor. "A true fibrous tumor of the ovary is a thing of very rare occurrence," says Wells; and he goes on to say, "It will be found that many cases reported as ovarian fibroids are in reality tumors beginning in the uterus, which overgrow and involve the ovary so as to disguise its natural appearance or conceal it altogether." Doran says, "I have never found a solid ovarian tumor to be formed of pure fibrous tissue, and strongly suspect that fibroids of the ovary are identical pathologically with fibroids of the uterus. All the solid tumors that I have seen removed at operations have proved to be sarcomatous or cancerous."

Dr. Formad, who kindly examined this specimen, sent the following report: "The solid tumor of the ovary proved, upon microscopical examination, to be a fibroma with decided sarcomatous change,—a fibro-sarcoma." A peculiarity of this tumor was its nodular character.

Dr. KELLY remarked that true fibroid of the ovary was very rare, and the specimen here presented was not, in his opinion, fibroid, but sarcoma. The only fibroid he had seen was one which he examined last spring. That tumor was about one centimetre in diameter, and, although attached to the ovary, lay in the grasp of an adherent fimbriated extremity, which cast some doubt upon the origin of the small growth. The so-called fibroid appears to be in every way analogous to the "fibroids" of the uterus and broad ligaments, and a useful diagnostic characteristic is the appearance of bundles of "sympathetically" enlarged fibres running from the hilum into the broad ligament.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held November 4, 1886, the President, A. JACOBI, M.D., in the chair.

THE MOVEMENTS OF THE HEART AND INTESTINES ILLUSTRATED BY PHOTOGRAPHY.

Dr. WILLIAM GILMAN THOMPSON read a paper illustrated by instantaneous photographs of the normal pulsating heart, taken in full diastole and systole and the various intervals between, and compared them with others showing the modifications in the form of the heart produced by thermic, chemical, and mechanical irritation. By a special form of apparatus he had been enabled to take six different views of the heart in motion within one second. This was something which in this country had never been accomplished before. The animal experimented upon was anæsthetized, the heart exposed, and a collar of white celluloid placed behind it, thus giving a white background. He had photographed the heart of the kitten, frog, pigeon, lizard, calf, rabbit, and other animals. The shape of the heart in these different animals differs considerably; but in general the longitudinal diameter exceeds the transverse by one-fourth during diastole. The movements and alterations in the form of the heart were determined largely by the thick-walled left ventricle. If the chest and pericardium were opened and artificial respiration kept up, the movements of the heart would be found greatly exaggerated; if artificial respiration were not kept up, the movements of the heart might be diminished. It was, therefore, too uncertain to enable him to draw conclusions under such circumstances as to what were the relations of the heart during motion to the other organs in the human subject. Much might be learned, however, with regard to the changes in form of the heart and the force of its pulsation.

Among the more important later observations which the author had made were the following. *First*, in most animals, the base of the heart descended very little, if at all, during systole. A prominent exception to this rule was seen in the frog. This movement was generally ascribed to elongation of the large arteries from increased tension during ventricular systole. *Secondly*, regarding changes in the diameters of the heart during systole there was much dispute among physiologists. In most animals there was slight shortening in the long diameter during systole; in the pigeon, however, there was slight lengthening. The transverse diameter was shortened usually twice as much as the longitudinal diameter in ventricular systole. The antero-posterior diameter was uniformly elongated by about one-eighth. *Thirdly*, the apex, when the pericardium was removed, was uniformly tilted forward, upward, and to the right, and the rotatory movement of the heart from left to right on its long axis occurred in excised hearts, as it did also in the heart *in situ*, but less extensively. The right ventricle lay so much higher and was so much thinner walled than the left that it had much less influence on the shape and movement of the heart than the left, especially near the apex.

It was a question in text-books whether the apex-beat of the heart was due to the thrust of the apex against the chest-wall or to the hardened anterior wall of the left ventricle, which in systole pressed against the chest. When the chest was opened, the apex was free to move through a much greater distance; and it was therefore unfair to conclude that, in the natural position, the apex-beat might not be due, at least in part, to the hardened anterior wall of the heart pressing against the chest; but the stroke of the apex also influenced this beat in animals.

The apex and whole contour of the heart were greatly modified by the influence of drugs. Those drugs which increased the force of systole rendered the apex of the heart sharper. Drugs which lengthened diastole rendered the apex blunter. If in the latter case an antagonistic drug was given, the apex would still remain rounder than normal. Uninfluenced by drugs, the surface of the heart during its movements was smooth; but it became more or less irregular under the influence of drugs. When the heart was slowly deprived of blood, the thick-walled left ventricle retained its shape pretty well; but, if held up, the right ventricle pouched downward. If the heart were now to be plunged into a liquid, it would fill itself by suction and assume a rounded form. The right ventricle continued to act feebly after the left had ceased its attempts, thus showing the apparently greater vitality of the right ventricle.

The auricles in systole were uniformly contracted, but to a small extent as compared with their own volume or the contraction of the ventricles. The independence of contraction between the auricles and the ventricles was shown by the photographs: the auricular systole overlapped the ventricular in point of time.

The extent of movement of the heart as a whole bore no definite relation to its size. It depended entirely upon the suddenness and force of systole, or the amount of work done by the heart.

In the photographs during systole the coronary arteries were seen to be prominent and distended. It had been questioned whether they were filled during systole or closed during systole by the cusps of the valves. If the latter were the case, these arteries must be filled during diastole by the elastic recoil of the aorta. The coronary arteries had been cut open during systole and found to spurt at that time; but it was shown in the photo-

graphs that their blood was dammed back during systole by the strongly-contracted ventricle, and, being thus put upon extra tension, it was only natural that the blood should spurt when their walls were cut. The author thought the illustrations proved that the coronary arteries received some blood-supply during diastole, and perhaps also during systole.

When the longitudinal and spiral fibres were destroyed by section, the circular fibres were made to contract, and almost entirely occluded the ventricular lumen in some cases. The contraction of the circular fibres was uniform and symmetrical. The papillary muscles were seen to stand out towards the centre of the ventricular cavities, and thus the photographs demonstrated that they had independent contractile power.

Of the various cardiac stimulants which he had tried, heat directly applied had the greatest influence, and apparently more upon the superficial muscles. Glenoin appeared to be the most active of the chemicals. Chloral seemed to be powerful in causing marked diastole, and the surface of the heart under its influence became irregular.

Dr. Thompson had also been successful in photographing the intestines, bladder, and diaphragm in motion. He showed photographs of the intestine which demonstrated peristaltic action towards both the pylorus and the anus; also the pendulum motion, and a circular contraction, which, when caused by pinching the intestine, produced considerable constriction. As to the peristaltic wave travelling in opposite directions, he thought it could only do good if the reverse motion were less in degree than the forward, as it would bring the ingesta more intimately in contact with the surface of the intestine and hasten their absorption.

Discussion was opened by Dr. A. H. Smith, and the President also made some remarks on the paper. The President was pleased to see American physicians thus ably competing in original investigations with the Europeans.

TWO OPERATIONS FOR INTESTINAL OBSTRUCTION.

Dr. W. GILL WYLIE reported the cases, and said that out of sixty-seven laparotomies which he had performed since January, 1885, he had selected six to report which were not strictly gynæcological cases. The first was one of laparotomy for complete intestinal obstruction. The patient was aged 50; menstruation had ceased four years. She had always been delicate. Eleven years ago a fibroid tumor was discovered in the pelvis. A physician introduced the uterine sound, which was followed by a violent attack of peritonitis. The patient remained in bed most of the time for a year. Since then she had had trouble in procuring movements of the bowels. Previous to the 6th of last October she had had more or less constant abdominal distention, with colic. During that night she began to suffer from intestinal obstruction in a more marked degree, having violent colic and vomiting. After these symptoms had continued for four days, during which time they were unable to produce a movement of the bowels, Dr. Wylie opened the abdomen. After breaking up some peritoneal cysts, the intestines were taken out of the abdomen, when a band of lymph, occluding the intestine at one point, was discovered and divided. The gut immediately surrounding was discolored, but not gangrenous. There was a fibroid involving the uterus and broad ligaments, which it was thought best to allow to remain. The patient made a good recovery, and had had less trouble with her bowels since the operation than she had had for some time before.

Dr. Wylie also related a case of perityphlitis, in which he had opened the abdomen and introduced a drainage-tube; one of tubercular peritonitis, in which he had practised permanent drainage; and made brief mention of the other three out of the six cases. He thought it happened not infrequently after laparotomy that a certain amount of peritonitis developed, leading to the formation of bands of lymph which to a greater or less degree obstructed the movements of the bowels; and he thought that if tympanitis and other symptoms pointed to the probability of the development of such bands after laparotomy, it would be better to cause a gentle movement of the bowels at an early date, sometimes as early as twenty-four hours after the operation, before such bands may have become firm in structure. He also thought that tapping abdominal tumors often led to the formation of such bands; and, as the procedure was calculated to give only temporary relief, he advised that the patient be sent to a competent gynæcologist for exploratory laparotomy, and, if found practicable, for operation for radical cure.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held October 27, 1886, the President, JOHN A. WYETH, M.D., in the chair.

TRANSPOSITION OF THE ABDOMINAL ORGANS—OBSTRUCTION OF THE GALL-DUCT.

Dr. MITCHELL PRUDDEN presented a part of the abdominal viscera and illustrated on the board a case of transposition of the abdominal viscera, especially with regard to the situation of the large intestine; a stone also obstructed the gall-duct. The patient was a middle-aged laborer, who had had a mild attack of gastritis, with anorexia, occasional nausea, and some diarrhœa. He lost flesh and strength, and when admitted to the hospital the liver was found enlarged and smooth,

extending over to the left side. There was nothing abnormal on palpation of the abdomen. There were râles at the apex of the right lung. The patient remained in much the same condition for a month, when, on September 5, without apparent cause, he had a slight chill and a rise of temperature to 103°. It then fell, but again rose to 106°; again fell to normal; but, two days later, again rose and fell; and then remained normal until October 12, when it rose and remained between 103° and 105° until just before death, when it fell, to rise again at death. The patient gradually failed: there were numerous crepitant râles over the lungs. He died October 20. A few days before death a hypodermic needle was introduced over the region where the gall-bladder should be, and a liquid containing a large number of bacteria was withdrawn. Subsequent insertion of the needle failed to withdraw anything but a few drops of blood.

The autopsy revealed the heart normal; the lung showed emphysema, chronic bronchitis, with interstitial pneumonia and œdema of the upper and lower lobes; the omentum was absent; the liver was drawn behind the free border of the ribs, was enlarged, the left lobe nearly as large as the right, in a condition of cirrhosis and moderate fatty degeneration. Among the transposed abdominal viscera, the organ to which he called especial attention was the large intestine. The cæcum was high up on the right side, and, after ascending to the free border of the ribs, the gut turned and passed directly to the left side; thence downward into the pelvis; then made a sharp turn and passed upward to near the umbilicus, and down again to form the rectum. The spleen was long and composed of three lobes, besides a number of supernumerary spleens, small in size. The position of the large intestine showed plainly that the hypodermic needle had entered what corresponded to the ascending portion of the colon.

Dr. ROOSEVELT said the patient had been under his care, and, gall-stone being suspected, especial pains were taken to elicit a history of gall-stones, but failed; yet at the autopsy the gall-duct was found occluded by a stone.

LESIONS INDUCED BY CORROSIVE SUBLIMATE.

Dr. ROOSEVELT presented the kidneys and large intestine of a negress, aged 19, who had died from the effects of swallowing twenty-five grains of corrosive sublimate in solution. Just after taking the poison she vomited a portion of it, and immediately began to experience severe pain in the throat and abdomen. After one and a half hours, severe purging began. It was probably five hours after taking the poison before the patient was brought to the hospital, when she passed some urine containing twenty per cent. of albumen and an abundance of casts, epithelium, pus, and blood. She stated that her feet and hands had swollen occasionally during the past year. Two days after admission it was recorded that she was suffering from constant purging, and that she had passed only an ounce and a half of urine since admission. The purging continued, also pain in the abdomen and vomiting, and on the 12th of May, six days after taking the poison, the patient died in collapse. The temperature had remained normal or subnormal save on one day, when it rose to 100°, and the night before death to above 102°. During her illness the kidneys had secreted only two ounces and five drachms of urine, containing the elements before mentioned. The kidneys at post-mortem were found to have undergone a degree of inflammation entirely destructive of their secretory function. The epithelium lining the uriniferous tubules was in various stages of degeneration and showed a great variety of form. A false or diphtheritic membrane covered the lining membrane of the intestine, much more marked in the large intestine. The mucous membrane of the stomach was reddened, swollen, and coated with mucus. A point of interest in the case was the almost complete suppression of urine unattended by any uræmic symptoms.

Dr. JOHN C. PETERS remarked that some years ago it was common, especially at the New York Hospital, to give large doses of corrosive sublimate in cases of Bright's disease, and the effect was marked: the patient passed a large amount of urine, and his symptoms were greatly relieved, although the chronic condition of the kidneys was not cured.

INTRA-CANALICULAR FIBROMA OF THE MAMMA.

Dr. SCHIFF presented a specimen under the microscope, being a portion of an intra-canalicular fibroid of the mamma, a little larger than a walnut in size.

Dr. Schiff also presented a hæmorrhoidal tumor first treated by injection with a solution of carbolic acid and afterwards extirpated.

Dr. PRUDDEN remarked, regarding the first specimen, that it was an excellent illustration of intra-canalicular fibroma of the mamma. Such specimens were rare, and when undergoing ulcerative change were liable to be mistaken for malignant growths.

Dr. WALDSTEIN said it had been shown that intra-canalicular fibromas of the mamma sometimes did become carcinomatous.

BRONCHO-PNEUMONIA WITH UNUSUALLY HIGH TEMPERATURE.

Dr. L. EMMET HOLT presented the lungs and kidneys of a child which died at the age of 11 months. The child had always been healthy until sixteen days before death, when

it was taken with symptoms pointing strongly to broncho-pneumonia. An interesting feature in the case was an elevation of the temperature at once to 105°, and a continued high temperature nearly throughout the disease, on two days reaching 106°, and on one occasion reaching 107°. Antipyrine had failed to keep the temperature down for any length of time, but a lukewarm bath would bring it down from two to four degrees; but after from three to five hours it would rise again. Suspecting some malarial complication, quinine was given, but without any effect. The autopsy revealed the usual lesions of broncho-pneumonia, and in addition some abscesses of the size of a pea in the apex of the right lung. There was parenchymatous nephritis, a moderate amount of entero-colitis, and a small amount of meningitis. No tubercles could be found.

Dr. J. Lewis Smith remarked that the nephritis would produce the elevation of temperature.

Dr. Holt regarded the nephritis as secondary, and not as the primary lesion.

Dr. Smith said he was reluctant to use antipyrine to reduce the temperature in the diseases of infancy. He would prefer salicylate of sodium.

Dr. Holt said he had not seen any bad effects from the use of antipyrine in children, although he had used it extensively; but it had not been his custom to give it in pneumonia.

CONGENITAL ABSENCE OF THE RIGHT LUNG—MALFORMED HEART.

Dr. J. Lewis Smith presented the heart and lung of a negro baby which died at the age of about two months. When about ten days old, the mother brought the child to his office and said that it had always gasped for breath. Dr. Smith found the respirations 70 to the minute, the pulse feeble and frequent. The temperature was not markedly elevated. Over the right side of the chest was complete dulness, which he supposed to be due to pleurisy with effusion; but on applying the ear over the area of dulness he could distinctly hear the respiratory sound, although a little feebler perhaps than on the left side. Bronchial respiration was not observed on the right side. The hypodermic needle withdrew only a few drops of blood from the right side. He sent the child to an experienced surgeon, who failed to withdraw any fluid from the right pleural cavity, and who came to the conclusion that there was probably pneumonic consolidation to account for the dulness on that side. A little less than two months afterwards Dr. Smith was sent for, and found the same physical signs; but the child had grown, and this fact, with the absence of elevation of temperature, led to a doubt as to the diagnosis of pleurisy. A day or two later he was notified that the child had died suddenly.

An autopsy was obtained, and a partial report on the specimen had been handed him by Dr. McNamara. The specimen consisted of the left lung, heart, and great vessels. Careful examination revealed at the point where the aorta arose a thin fragment of lung-tissue which had never been dilated. This was the rudimentary right lung. The trachea branched into the right and left bronchi, the right becoming lost about a quarter of an inch from the bifurcation. The heart revealed a large left ventricle with three openings,—one into the aorta, one into the auricle, and the third through the septum which communicated with the right pulmonary artery. There were but one auricle and one ventricle. The specimen was referred to the Committee on Microscopy.

STENOSIS OF THE MITRAL VALVE, ETC.

Dr. Frank Ferguson presented a heart which illustrated hypertrophy with dilatation of the cavities, together with mitral stenosis; the tricuspid opening was about the size the mitral should be in health. All the viscera were congested. The liver presented the appearance of the so-called "nutmeg liver." The patient had suffered from dyspnœa. There had been pulsation in the veins of the right side of the neck, râles over the lungs, slight general jaundice, etc.

REVIEWS AND BOOK NOTICES.

The Curability and Treatment of Pulmonary Phthisis. By S. Jaccoud, Professor of Medical Pathology to the Faculty of Paris, etc. Translated and edited by Montagu Lubbock, M.D. (London and Paris), etc. New York, D. Appleton & Co., 1885. Cloth, 8vo, pp. 407.

The new ideas which have lately been accepted of the etiology of phthisis pulmonalis, and the accumulated experience of the profession as to the value of climatic stations in its treatment, have warranted the statement that this disease may be not only ameliorated by treatment, but actually cured. This work by Professor Jaccoud is timely, and contributes considerable from his personal experience to the elucidation of the subject. The curability of pulmonary consumption is first taken up, and is followed by a consideration of the conditions of curability and prophylactic treatment, and the work concludes with the therapeutic method, and especially the climatic treatment. In the latter part of the work the results of Professor Jaccoud's personal observation and studies with regard to health-resorts in Europe are communicated, with judicious recommendations with regard to the selection of a place of abode by consumptives.

A Treatise on the Diseases of Infancy and Childhood. By J. Lewis Smith, M.D., Clinical Professor of the Diseases of Children in Bellevue Hospital Medical College, New York. Philadelphia, Lea Brothers & Co., 1886. Octavo, 867 pages, 40 illustrations. Cloth, $4.50; leather, $5.50.

The sixth edition of Lewis Smith's valuable treatise on diseases of children comes to hand thoroughly revised and with some additions. The usual diseases of infancy and childhood are discussed, and their therapeutics rationally considered; this being preceded by nine chapters in which various physiological and hygienic topics of great importance in this connection are reviewed. Maternal impressions, the causes of infant mortality, the proper physical conditions for lactation, artificial feeding, selection of a wet-nurse, bathing, clothing, and exercise, each are considered and practical suggestions given in relation thereto. We look upon this as the standard American work on diseases of children, and its clearness and directness of language make it specially valuable for students' use.

The Ten Laws of Health; or, How Diseases are Produced and Prevented: and Family Guide to Protection against Epidemic Diseases and other Dangerous Infections. By J. R. Black, M.D. Philadelphia, J. B. Lippincott Company, 1885.

A compendious treatise upon personal hygiene in popular form is presented in this readable work, which should have been noticed earlier in these pages. The first part is taken up with the discussion of ten so-called "laws of health," in which the most prominent causes of morbid conditions are reviewed. The second part considers the germ-theory of disease, and makes very practical and valuable suggestions with regard to disinfection and general management of the ordinary zymotic diseases. We feel confident that much good can be done by the circulation of such works among the laity.

The Disorders of Menstruation: A Practical Treatise. By John N. Upshur, M.D., Professor of Materia Medica and Therapeutics in the Medical College of Virginia, Richmond, Virginia. New York and London, G. P. Putnam's Sons, 1886. 12mo, pp. 200.

This little work is apparently a plea for the intelligent and conscientious management, as opposed to the routine treatment, of a series of disorders to which a large portion of the sufferings of women are directly or indirectly attributable. It is written in clear style, and, if widely read, might result in an improvement in practice, in some directions at least, that could not fail to redound to the credit of the profession.

Archives of Ophthalmology. Volume XV. Nos. 2 and 3. G. P. Putnam's Sons, New York.

These numbers, issued separately, are at hand, and fully sustain the reputation of the *Archives*. We note an improvement over previous numbers in that the articles are short and comprehensive, and free from the prolixity which often has marked the translated articles. The usual Report on the Progress of Ophthalmology is appended to each number. A brief summary of the more important articles will appear in our next Report on Ophthalmology.

Venereal Memoranda. A Manual for Student and Practitioner. By P. A. Morrow, M.D., etc. New York, William Wood & Co., 1886.

Gonorrhœa, chancroid, and syphilis are considered in a series of aphorisms, and due consideration given to prophylaxis and treatment of venereal diseases. A valuable collection.

NEW REMEDIES AND CLINICAL NOTES.

Post-Febrile Neuritis.—One of the most important advances made during the past year in neurology is the recognition of the great frequency of neuritis. It is now known that many forms of paralysis and disorders of sensation commonly attributed to cerebral and spinal changes are really due to inflammation of the peripheral nerves. It is only within a very recent period that alcoholic neuritis has been determined to be a distinct disease. Still later, we have proof that many cases of paralysis following the infectious fevers are really due to a peripheral neuritis. Of all the acute febrile diseases, diphtheria is the most frequently followed by these changes. So profound are they in the peripheral nerves after this disease at times that recovery is hopeless. The vast majority of cases, however, recover completely.

The paralysis which is occasionally seen following typhoid fever has been almost universally attributed to a subacute poliomyelitis, but from the recent researches of Pitrès and Vaillard it is plain that it is more frequently due to a peripheral neuritis. In several cases they found marked degenerative changes in the ulnar, musculo-spiral, peritoneal, saphena, and other nerves. These changes closely resemble those found in the nerves in cases of fatal diphtheritic paralysis. Not only is peripheral neuritis a frequent effect of the acute infectious diseases, but it is also seen in those of the chronic infectious class. The same observers have found degenerative changes during the course of chronic tuberculosis in the peripheral nerves.—*Canada Med. and Surg. Journal.*

A Solvent for Sordes.—Dr. A. D. MacGregor speaks highly of boric acid as a topical application in the unhealthy condition in which we frequently find the mouth, tongue, and teeth in severe cases of typhoid fever. He says, in the *British Medical Journal*, "The mouth is hot; the lips dry, cracked, and glued to the sordes-covered teeth by inspissated mucus and saliva; the tongue dry, or even glazed and hard, brown or black, crusted with a fetid fur. Under these circumstances a pigment containing boric acid (thirty grains), chlorate of potassium (twenty grains), lemon-juice (five fluidrachms), and glycerin (three fluidrachms) yields very comforting results. When the teeth are well rubbed with this, the sordes quickly and easily becomes detached; little harm will follow from the acid present. The boric acid attacks the masses of bacilli and bacteria; the chlorate of potassium cools and soothes the mucous membrane; the glycerin and lemon-juice moisten the parts and aid the salivary secretion."

The Relation between Gastric Ulcer and Anæmia.—Circular ulcers of the stomach, according to Silbermann, of Breslau, are favored in their development by that kind of anæmia in which there is deficiency of the hæmoglobin. All the theories for the production of gastric ulcer are satisfied in this condition,—viz., arterial anæmia (Klebs), venous hyperæmia of the gastric mucosa (Key), venous stasis in the hepatic vessels (Gunsberg), circumscribed hemorrhages (Virchow), and, finally, diminished alkalinity of the blood.—*Lancet.*

MISCELLANY.

The Progress of Cremation.—The crematory near New York has during its short career had more cremations than any other institution of the kind in the country, but its business does not now attract the attention it did at first. The novelty of the thing has worn off, and very likely the desire of people to be burned instead of buried has somewhat lessened.

In Italy, where the method has been most earnestly advocated, it has not made very great progress.

The city of Milan has been the headquarters for the advocates of cremation, but even here the furnaces are not often lighted, though the death-rate continues as usual.

In Rome it has had no acceptance at all, and the Pope has recently issued some decrees which make it very evident that the Papacy will fight bitterly what it calls a pagan custom. All faithful Catholics are forbidden to affiliate with any cremation society, and no one is to be permitted to order or facilitate cremation, even when the testator should have directed this kind of sepulture for himself and when his executors and next of kin are desirous of carrying out his wishes.

Appointment of a Commission on the Mode of Capital Punishment.—The New York Legislature, at its recent session, passed a law of considerable general interest. It provided for a commission to investigate and report to the Legislature, on or before the fourth Tuesday of January, 1887, "the most practical and humane method known to modern science of carrying into effect the sentence of death in capital cases." The following persons were appointed commissioners: Elbridge P. Gerry, of New York City; Dr. A. P. Southwick, of Buffalo; and Matthew Hale, Esq., of Albany. This law is the outcome of a determined effort on the part of many citizens to have a competent commission investigate and see if a better method of inflicting the death-penalty than hanging could be devised. There is no public sentiment in New York averse to the infliction of death as a punishment for murder, but hanging is repulsive for many reasons. The Medico-Legal Society has discussed the subject, and many methods have been proposed in place of the scaffold and noose. The report of the commission will be awaited with considerable interest.

The Medical Education of Women in Edinburgh.—After an interval of more than twelve years, women are now admitted to medical education in Edinburgh: six women have entered upon the first year's course of studies.

Duhring's "Treatise on Diseases of the Skin" has just been published in the Russian language. This is an additional compliment to a Philadelphia author, whose work has already appeared in two editions in English and has been translated into French and Italian.

NOTES AND QUERIES.

OBITUARY.

Dr. Joseph Gibbons Richardson, Professor of Hygiene in the Medical Department of the University of Pennsylvania, and member of the Board of Health of this city, died of apoplexy on the 13th instant, in the fifty-first year of his age. A native of Philadelphia, and a member of the Society of Friends, he pursued his studies at the University of Pennsylvania, from which he received his medical degree in 1862. Subsequently he was resident physician in the Pennsylvania Hospital and the Wills Hospital, and resided for five years at Union Springs, Cayuga County, New York, returning to Philadelphia as his place of permanent abode in 1868. He was the author of a work on Medical Microscopy, and a frequent contributor to medical journals. He was Secretary of the Biological and Microscopical Section of the Academy of the Natural Sciences, a Fellow of the College of Physicians, a member of the Philadelphia County Medical Society and of the American Medical Association, and a corresponding member of the Société Française d'Hygiène. For several years he was microscopist to the Pennsylvania Hospital and Visiting Physician to the Presbyterian Hospital of this city.

Professor Paul Bert, formerly Minister of Public Instruction under the Gambetta administration, and of late the

resident Minister of France at Hué, Anam, died at his post of duty on November 11, a victim of the climate. He was born October 19, 1833, at Auxerre, France, pursued his studies in Paris, and in 1868 was elected Professor of Physiology in the Faculty of Science of Paris. In 1875 he received the biennial prize of the Institute for physiological research. He was elected a member of the National Assembly in 1872, and subsequently became prominent by his labors to advance popular education.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 7, 1886, *TO NOVEMBER* 20, 1886.

MAJOR J. P. WRIGHT, SURGEON.—From Department of Texas to Department of Missouri, for duty as attending surgeon at Leavenworth Military Prison, Fort Leavenworth, Kansas.

MAJOR W. H. FORWARD, SURGEON.—From duty as attending surgeon at Headquarters, Division of the Missouri, and examiner of recruits at Chicago, Illinois, to Department of Dakota.

MAJOR V. B. HUBBARD, SURGEON.—From Department of Arizona to duty as attending surgeon at Headquarters, Division of the Missouri, and as examiner of recruits at Chicago, Illinois.
S. O. 257, A. G. O., November 4, 1886.

MAJOR C. R. GREENLEAF, SURGEON.—Relieved from duty at Columbus Barracks, Ohio, and ordered for duty as attending surgeon at Headquarters, Division of the Missouri, and examiner of recruits at Chicago, Illinois. S. O. 268, A. G. O., November 17, 1886.

MAJOR HENRY R. TILTON, SURGEON.—Relieved from the duties of attending surgeon at the Headquarters of Division of the Pacific and Department of California. S. O. 96, Division of the Pacific, November 9, 1886.

MAJOR W. E. WATERS, SURGEON.—Ordered from Fort Spokane to Vancouver Barracks, Washington Territory, for duty at that post. S. O. 197, Department of Colorado, November 8, 1886.

PARAGRAPH 8, S. O. 257, A. G. O., November 4, 1886, is so amended as to direct Major V. B. Hubbard, Surgeon, to report in person to the commanding officer, Columbus Barracks, Ohio, for duty. Paragraph 3, S. O. 268, A. G. O., November 17, 1886.

MAJOR D. G. CALDWELL, SURGEON.—Granted leave of absence for one month, with permission to apply for twenty days' extension. S. O. 150, Department of the Platte, November 12, 1886.

MAJOR CHARLES SMART, SURGEON.—Granted leave of absence for one month. S. O. 265, A. G. O., November 13, 1886.

CAPTAIN L. Y. LORING, ASSISTANT-SURGEON.—Sick-leave of absence further extended three months, on surgeon's certificate of disability. To be relieved from duty in Department of California, and, on the expiration of his present sick-leave of absence, will report by letter to the Surgeon-General of the Army. S. O. 262, A. G. O., November 10, 1886.

CAPTAIN E. B. MOSELEY, ASSISTANT-SURGEON.—Assigned to duty as attending surgeon in San Francisco, California. S. O. 94, Division of the Pacific, November 1, 1886.

CAPTAIN HARRY O. PERLEY, ASSISTANT-SURGEON.—Granted leave of absence for four months on surgeon's certificate of disability. S. O. 257, A. G. O., November 4, 1886.

FIRST-LIEUTENANT CHARLES C. BARROWS, ASSISTANT-SURGEON.—Ordered to report to commanding officer, St. Francis Barracks, St. Augustine, Florida, for duty at Fort Marion. S. O. 180, Division of the Atlantic, November 10, 1886.

FIRST-LIEUTENANT C. N. B. MACAULEY, ASSISTANT-SURGEON.—Granted leave of absence for twenty days. S. O. 118, Department of Dakota, November 8, 1886.

FIRST-LIEUTENANT JOHN L. PHILLIPS, ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply at Headquarters, Division of the Missouri, for an extension of one month. S. O. 116, Department of Dakota, November 2, 1886.

FIRST-LIEUTENANT W. D. CROSBY, ASSISTANT-SURGEON.—Ordered from Fort McDowell, Arizona Territory, to Fort Bowie, Arizona Territory. S. O. 110, Department of Arizona, October 29, 1886.

FIRST-LIEUTENANT CHARLES B. EWING, ASSISTANT-SURGEON.—Ordered from Fort Supply, Indian Territory, to Fort Leavenworth, Kansas, for duty. S. O. 126, Department of the Missouri, November 6, 1886.

FIRST-LIEUTENANT FRANCIS J. IVES, ASSISTANT-SURGEON.—Ordered to proceed to and take station at Fort D. A. Russell, Wyoming. S. O. 145, Department of the Platte, November 4, 1886.

FIRST-LIEUTENANT E. R. MORRIS, ASSISTANT-SURGEON.—Ordered from Fort Bayard, New Mexico, to Fort Thomas, Arizona Territory. S. O. 110, Department of Arizona, October 29, 1886.

APPOINTMENTS.

LIEUTENANT-COLONEL JOHN MOORE, ASSISTANT-MEDICAL PURVEYOR.—To be Surgeon-General of the Army, November 18, 1886.

ROBERT R. BALL.—To be Assistant-Surgeon, with the rank of First-Lieutenant, November 19, 1886.

PAUL CLENDENIN, First-Lieutenant and Assistant-Surgeon, November 5, 1886.

CHARLES L. G. ANDERSON, First-Lieutenant and Assistant-Surgeon, November 5, 1886.

PROMOTIONS.

MAJOR JOSEPH C. BAILY, SURGEON.—To be Assistant-Medical Purveyor, with the rank of Lieutenant-Colonel, November 18, 1886.

CAPTAIN CHARLES L. HEIZMANN, ASSISTANT-SURGEON.—To be Surgeon, with the rank of Major, November 18, 1886.

CAPTAIN ROBERT M. O'REILLY, ASSISTANT-SURGEON.—To be Major and Surgeon, November 1, 1886, *vice* Clements, deceased.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FOR THE TWO WEEKS ENDED NOVEMBER 20, 1886.

PASSED ASSISTANT-SURGEON OLIVER DIEHL, U.S.N.—Granted three months' leave of absence from the 26th of October.

THEORON WOOLVERTON, SURGEON, U.S.N.—Detached from the U.S.S. "Shenandoah," proceed home, and wait orders.

V. B. C. MEANS, ASSISTANT-SURGEON, U.S.N.—Detached from the U.S.S. "Shenandoah" and ordered to Receiving-Ship "Independence."

J. B. PARKER, SURGEON, U.S.N.—Detached from the U.S.S. "Swatara," proceed home, and wait orders.

JOSEPH SHAFER, ASSISTANT-SURGEON, U.S.N.—Detached from the U.S.S. "Swatara," proceed home, and wait orders.

PASSED ASSISTANT-SURGEON FRANCIS S. NASH, U.S.N.—Ordered to special duty, Smithsonian Institution, November 26, 1886.

MEDICAL-INSPECTOR A. C. RHOADES, U.S.N.—Ordered to special duty attending officers and families in New York City.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED NOVEMBER 13, 1886.

AMES, R. P. M., PASSED ASSISTANT-SURGEON.—To proceed to Vineyard Haven, Massachusetts, as inspector, November 10, 1886.

URQUHART, F. M., PASSED ASSISTANT-SURGEON.—Granted leave of absence for seven days, November 8, 1886.

WASDIN, EUGENE, PASSED ASSISTANT-SURGEON.—Granted leave of absence for seven days, November 11, 1886.

MAGRUDER, G. M., ASSISTANT-SURGEON.—Relieved from duty at Norfolk, Virginia; assigned to duty at Marine Hospital, Chicago, Illinois, November 10, 1886.

PHILADELPHIA, DECEMBER 11, 1886.

CLINICAL LECTURE ON HEMORRHAGE FROM THE STOMACH.

Delivered at the Pennsylvania Hospital, Philadelphia, November 20, 1886,

BY J. M. DA COSTA, M.D., LL.D.,

Professor of Theory and Practice of Medicine and of Clinical Medicine in the Jefferson Medical College.

GENTLEMEN,—The first case I will present to you is that of the patient, about 40 years of age, occupying bed No. 6 in the Men's Medical Ward. He has been in the hospital for some time; his history prior to his admission is that he had been a hard drinker. He passed a tape-worm some nine years ago. He is usually a well man, except when suffering from the effects of drink. He says that last spring he stopped drinking to excess. About five months before admission into the ward (which was on the 3d of November) he vomited blood; he had never done so before. Since that time he has been subject to flatulent dyspepsia.

Upon inquiry he now tells us that he had been troubled with indigestion and had "belched up wind for a good while;" that is, the flatulent dyspepsia preceded the vomiting of blood, although it has been worse since this occurred; he also had been constipated before he vomited blood. His appetite had been poor, and he could not eat much, for a month or two before it came on; and for a couple of weeks he had had morning vomiting before breakfast. In other words, he presented the ordinary symptoms of gastric catarrh.

Shortly before coming here he had a second hemorrhage from the stomach. He was distributing hand-bills at the time, and had walked a good deal. He was taken ill upon the street, and it is stated in the notes that he fainted and fell upon the pavement. He estimates the amount of blood that he vomited to be between a pint and a quart. The blood was mainly dark-colored and clotted; some of it looked fresh. This was five days before admission, but he continued to vomit blood even after he came under treatment. He was brought here as a case of gastric ulcer.

It was the second attack for which he applied for relief. From the time of the previous one, five months before admission, he had been dyspeptic up to the second attack, which occurred five days before admission, and which was so severe as to cause him to faint and fall in the street. Subsequently he vomited a little blood every day until he came in, and indeed the bleeding did not stop until the second day after admission. Now that we have a clear history of his hæmatemesis, let us inquire more fully into his dyspeptic symptoms. He states that the vomiting comes on usually a short time after eating, but it may come on at irregular times. He has had very little pain in his stomach; he only complains of a little "wind-pain" at times. He appears to have a great dread of solid food and avoids it; he declares that if he ate it "it would kill him." Since admission he has been on liquid diet, but he says that previously he had noticed that he had considerable pain after eating solids. His bowels are almost always constipated. He has no cough. He is very anæmic-looking. His appetite, he says, remains good. After the first day, when he was vomiting dark blood four or five times daily, the discharges from the bowels were little except blood. He has considerable thirst; his mouth and throat are dry.

Now, gentlemen, upon proceeding to examine our patient, you will notice, first, that he is strikingly anæmic. Look at his hands, his conjunctivæ, his tongue! His tongue is pale in spite of a furry coat upon it. He has no disease of the lungs or of the heart; in truth, he has a very well developed chest. There is a systolic basic intracardiac murmur to the left of the sternum, due to the condition of his blood. He has no sponginess of the gums, and no blue line upon them. There is no epigastric soreness, and no enlargement of the spleen. The area of liver-dulness is small, barely extending to the margin of the ribs, and there is no dropsy. I cannot detect any epigastric tumor; but he has a very large rectus muscle upon the right side which might be mistaken for one. He has no pain or tenderness in the back. The liver, as demonstrated by percussion, does not extend upward; it is not displaced, although it barely reaches the costal border.

What is the matter with this man? I

have told you that he was supposed to have had a gastric ulcer. Now, has he a gastric ulcer or not? We come now to a point of much interest, which I will briefly discuss. Here is a man who, most undoubtedly, has had hemorrhages from the stomach, not only one, but a series of them, sufficiently severe to cause him to faint in the street and afterwards to lead him to the hospital, and sufficient to cause profound anæmia. We have also the testimony of those who saw him vomit after admission, and the evidence of the tarry discharges from the bowels. I repeat the question, Has he gastric ulcer or not?

This leads to a discussion of the causes of hemorrhage from the stomach.

Hemorrhage from the stomach is most frequently due, in cases of organic disease, to ulcer or cancer of the organ; where organic disease is not present, it is most often caused by changes in the blood, as, for instance, those which attend purpura and scurvy. Again, the hemorrhage may be due to venous congestion of the stomach, the result of disease of the liver or the spleen, as in some cases of malaria, or accompanying interstitial hepatitis. I might also mention the possibility of hemorrhage from the stomach as a symptom of some acute disease, such as yellow fever, or hemorrhagic malarial and other forms of malarial fever; but these will not enter into our discussion of the case, since he has not a fever-temperature. Casting these acute febrile hemorrhages out of consideration, as excluded by the temperature-record of the patient, which I find is rather below than above the normal, let us take up the other causes for discussion.

Let me state here that the urine has been repeatedly examined for albumen and sugar with a negative result, which is an additional reason—the absence of albumen, at least—for excluding hemorrhagic malarial fever. We may also set aside purpura and scorbutus, since the other essential features are wanting. I may also exclude disease of the spleen, a cause of hæmatemesis much more frequent than generally recognized, by the results of our physical examination.

Taking up organic diseases of the stomach, we ask first, Is it cancer? The absence of severe pains, the irregularity of the vomiting, and the non-existence of a tumor and decided tenderness in the epigastric region, lead me to reject the hypothesis of its being a case of cancer of the stomach.

By the process of exclusion we have now been reduced to two diseases. Has this man ulcer of the stomach? Or has he a disease of a neighboring organ, causing chronic congestion of the gastric mucous membrane and favoring the occurrence of rupture of the smaller vessels? Is it a case of disorder of the stomach with dyspeptic symptoms, due to disease of the liver? In favor of gastric ulcer—and what has given rise in this case to a belief in the existence of a gastric ulcer—is the free hemorrhage. His age is also in favor of this view, and his sex does not oppose it; although it would be stronger as a supposition in the case of a woman than of a man. The pain and gastric disorder are also in its favor. Still, I must pronounce against it, because there is no evidence of local soreness: no spots of tenderness upon pressure are found either in front or back. These are the rule in gastric ulcer. But what is more significant is this: he has no pain whatever, or very slight pain, immediately after taking food. From his very vague answers to my questions upon this point, you could see that the pain certainly is not severe. Even a drink of water would give pain in gastric ulcer at some time or other. He is free from pain while taking soft food; he abstains from solid food because of the flatulence and weak digestion, and not because of the pain. Therefore, from the absence of localized tenderness and the absence of pain after eating, I conclude that it is not a case of gastric ulcer. I admit that there are cases of gastric ulcer which are latent; but the features of the case do not warrant this explanation, and the history decidedly opposes it.

What, then, is the matter with this man? I have already indirectly answered this question. It is a case of hepatitis due to alcohol; and this hepatitis has interfered with the circulation in the gastric mucous membrane, and caused congestion and passive hemorrhage. The persistent indigestion is in favor of this view, and the character of the hemorrhage is in accord with this supposition. The only thing against it is the absence of dropsy. I can account for it only on the grounds that the portal congestion has been relieved by the bleeding, or that possibly the malady has not reached the stage of dropsy.

As his stomach has recovered to some extent, we may direct our attention to the condition of the liver, which is plainly that of cirrhosis caused by alcohol. He shall have bichloride of mercury (gr. $\frac{1}{40}$ thrice daily) and a restricted liquid diet, supplemented, if necessary, by rectal alimentation with peptonized broths or pancreatinized milk. The mercury is given with the view of its effect upon the chronic process of inflammation and increase of connective tissue which is constantly going on in the interior of this man's liver. I would also like to give him iron, to improve his anæmia, and will probably do so later; but I prefer not to order it now, on account of the existing catarrh, and irritability of the stomach.

ORIGINAL COMMUNICATIONS.

A CASE OF PERITONITIS IN ENTERIC FEVER, TERMINATING IN RECOVERY.*

BY J. C. WILSON, M.D.,

Physician to the Hospital of the Jefferson Medical College, etc.

THE following case, very recently under observation, is brought to your attention for two reasons. First, because, as illustrating the fortunate termination of general peritonitis occurring as a complication, or, rather, as a sequel, of enteric fever, it is sufficiently rare to be of interest. Secondly, because it serves as the occasion for some remarks upon the pathology of this complication and for the discussion of measures of treatment which in the graver cases may hereafter be the means of occasionally saving life.

Agnes M., 12 years of age, a school-girl, was taken ill rather suddenly, with headache, dizziness, and inability to take food, August 22, 1886. She continued to be about, however, until the 26th, when I saw her for the first time. The patient is a puny child, lean, and deaf in consequence of suppurative otitis occurring in the course of severe scarlet fever some years ago. Her mother is the care-taker of a large house used for office purposes. The nursing was not in all respects satisfactory, but my directions were intelligently and faithfully carried out, and there is no reason to believe that any error in the mother's management of the case was operative in bringing about the intestinal complication.

The illness speedily showed itself to be well-characterized, mild enteric fever. The tongue was coated with a whitish-yellow fur; it was red at the tip and edges, and remained so throughout. She had no appetite, and very moderate thirst. The abdomen was slightly distended, tender in the right iliac fossa and around the navel. The bowels were at first confined, later rather loose, although at no time did the stools exceed four in the twenty-four hours. There was moderate enlargement of the spleen. The heart's action was frequent; pulse 100 to 120,—after the first week usually dicrotic. She had a slight cough, and coarse mucous râles were at times observed. The nose bled a few drops on three occasions. The headache ceased on the eighth day, and from that time till defervescence there was slight delirium alternating with somnolence, from which the patient could be easily aroused, only, however, to fall again quickly into the same drowsy state. Upon the sixth day the eruption made its appearance. The rose-spots were few in number, and ceased to appear about the sixteenth day. The urine was of rather small amount, and on repeated examination free from albumen.

The febrile movement was moderate: the highest temperature observed was 103° F. on the evening of the sixth day. With this exception, no temperature exceeding 102.5° F. was recorded. The evening range was, with these exceptions, between 101.5° and 102° F.

The treatment consisted of small doses of carbolic acid and tincture of iodine. Upon the fourth day of the illness, and again upon the sixth, two-grain doses of calomel were administered.

The diet was restricted to liquids, and the patient was not allowed to rise from the bed for any purpose whatever. From the middle of the second week a teaspoonful of whiskey was given in milk every sixth hour.

Defervescence began about the middle of the third week. On the seventeenth day the morning temperature was normal; on the twentieth, the evening temperature was 99.4° F.; and on the twenty-first, defervescence was complete. The patient was now quite weak, but bright, and clamorous for "something to eat." No solid food was permitted, however, until the morning of September 13, the twenty-third day after the beginning of the sickness. A soft-boiled egg, into which was stirred a little finely-crumbled stale bread, was given about 11 A.M. Half an hour later the patient complained of severe pain in the abdomen, and had a chill, which was followed by vomiting. At 7 P.M. I saw her. The vomiting had ceased, but there was intense nausea, with thirst; the tongue was dry; the belly tense and tender; the pulse small, tense, and 140 in the minute; decubi-

* Read at a Clinical Meeting of the Philadelphia County Medical Society, November 17, 1886.

tus dorsal, with knees drawn up; the axillary temperature was 104.5° F. There were not at this time, nor could I find upon careful questioning that there had been, any signs of collapse after the chill. Two hours later Dr. W. W. Keen saw her with me. The temperature had fallen a degree, and the pulse to 120. Upon palpation the whole belly was exquisitely tender, but we both thought that the focus of tenderness was in the right iliac fossa. The pain was general over the abdomen.

The treatment consisted of half a grain of opium by suppository every six hours, and forty drops of paregoric every two hours. The belly was smeared with equal parts of sweet oil and turpentine and covered with a light poultice. A little iced whiskey-and-water from time to time was allowed, but nothing in the way of food was permitted during the night. Early the following morning Dr. Keen saw her again. The general symptoms remained the same. The temperature had, however, fallen to 101° F., and the pulse was fuller, though still 120. The full opium-treatment was continued, so also was the poultice. Light liquid food was prescribed and retained. From this time catheterization was necessary for several days. The urine contained a trace of albumen and a few hyaline casts. Nine days later defervescence, which was gradual, was complete. The belly was still swollen, but less tender. The greatest tenderness was on the right side, in front of the border of the ilium; here there was also local dulness upon percussion.

At the expiration of three weeks recovery seemed to be complete; yet on two occasions within the last month a larger meal than usual has been followed by fever, lasting two or three days, and by tenderness in the right iliac fossa. For the past two weeks the patient has been apparently in her usual health.

Murchison enumerates the following lesions as causing the complication of peritonitis in enteric fever:

Softened infarctions in the spleen; the bursting into the peritoneum of a softened mesentery gland; an abscess in the wall of the urinary bladder or in the ovary or in the sheath of the rectus muscle bursting into the peritoneal cavity; ulceration of the gall-bladder; the propagation by continuity of inflammation from the mucous to the peritoneal coat of the intestine without perforation; and, finally, and by far the most frequently, perforating ulceration of the bowel.

When recovery takes place it is impossible to say with certainty what the lesion has been, but a consideration of knowledge derived from clinical and from post-mortem examinations warrants us in dividing cases of peritonitis occurring in typhoid fever into two perfectly well characterized groups. The case which I have reported well illustrates the first group; and cases with suddenly-occurring collapse, evidences of peritonitis not followed by improvement and ending fatally in thirty-six or forty-eight hours, illustrate the second group. Between these two groups there is the widest difference. In the systematic works on typhoid fever a limited number of cases of recovery from peritonitis in the course of the disease are recorded. At the same time this complication is of the most serious gravity, and likely in the larger proportion of cases to terminate fatally. The anatomical condition in those cases that recover is fairly well known, partly from the post-mortem examination of cases which have died at a later period from other causes, and partly from the clinical history of cases in which a circumscribed abscess has formed and has been evacuated (either spontaneously or by operation) some weeks or months later.

The most favorable type of the first group of cases may be said to be those in which there is a local peritoneal inflammation, the result of extension from the mucous to the serous surface, without direct penetrating lesion of the wall of the gut. Here, under favorable circumstances, the inflamed patch of intestine becomes adherent by lymph to an adjacent coil of intestine or to other structures, and perforation is averted by the patch which is thus put upon the weakened bowel. There are numerous post-mortem records which show that even where sloughing has led to an actual solution of continuity of the wall of the gut, such adhesions have taken place before there has been any considerable extravasation of the intestinal contents into the peritoneal cavity, and although the patient may present the appearances of general peritonitis, as in the case reported, nevertheless recovery takes place.

From the most favorable instances of this kind there must be by gradations less and less favorable pathological conditions until the case becomes one of serious gravity in consequence of actual extravasation of fecal matter and the formation of a local peritonitis in which, however, the conditions are not such as to make a fatal result unavoidable. From this point, however, to the class of cases which I have designated

as forming the second group the transition is abrupt. Typical cases of this kind are occasionally encountered clinically and in the post-mortem room. As a consequence of the direct death of a portion of the ulcerated wall of the gut, the floor of the ulcer has absolutely dropped out, allowing the extravasation of intestinal contents. A similar condition of things may result from the laceration of an ulcer which has reached down to or through the muscular coat, and has remaining a very slight support at its base. Here, as the result of active peristalsis, however induced, the wall of the ulcer gives way. The bases of deep ulcers, even when not in a condition of sphacelus, are, as the result of inflammatory infiltration, inelastic, brittle, readily liable to undergo laceration. This accident causes the irregular linear perforations occasionally seen. I do not stop to speak of the rupture of large abscesses, or of abscesses in the wall of the gall-bladder, or of rupture of the spleen. These catastrophes give rise to the large extravasation of foreign matters into the peritoneal cavity.

What have we in this second group of cases? Not only an entirely different pathological condition, but also a different clinical picture from that presented by the first group. The evidences of active peritoneal inflammation, chill with high temperature, vomiting, and other well-recognized symptoms, may be absent, the condition manifesting itself simply by the occurrence of profound and intractable collapse. Indeed, sudden collapse is the striking feature in the picture presented by the second group of cases. This collapse in many instances points to such a shock to the nervous system as will terminate fatally in the course of a few hours: such a shock as would be produced by a penetrating gunshot-wound of the abdomen.

This leads me to the point which I have had in mind in bringing the report of this case before you. I take it for granted that almost every case of free extravasation of intestinal contents, however small in amount, into the peritoneal cavity terminates fatally. There is little reason to believe that any case of this kind recovers. It is important to note that the cases of peritonitis in enteric fever in which recovery is possible can be clinically distinguished from those which will terminate rapidly in death. The clinical picture of the two conditions is almost as distinct as are the pathological lesions. Where there is extravasation of the intestinal contents into the peritoneal cavity, the collapse is like that caused by the escape of an amount of foreign matter the result of a perforating gunshot-wound of the intestine. The proposition which I submit for discussion arises directly from a consideration of the matter in this way. Until within a few years, no surgeon realized the possibility of treating cases of gunshot-injury of the abdomen with perforation of the intestine and the escape of blood and fecal matter by the operation of laparotomy, washing out the peritoneal cavity, excising bruised and lacerated portions of the intestine and bringing the parts together by suture. Yet this is now the recognized procedure in such cases, and has been of late practised in many instances with success in cases that under the old plan of opium and expectancy would have inevitably perished.

Are we ready to adopt the same measures in perforation of the intestine with similar conditions as regards the peritoneal cavity and a like helplessness as regards cure by opium and expectancy in our cases of enteric fever? Recognizing the two groups of cases I have described, and being, as we are, able to refer almost all cases to either one or the other of them within a few hours of the development of the symptoms, are we prepared to decide —and to do so with the necessary promptness—upon those operative procedures by which alone in the second group the life of the patient may be saved?

Granted that the chances of a successful issue are heavily against you; that the patient is in the midst or at the end of a long sickness; that his tissues are in the worst state to stand the injuries of the surgeon's knife; that the lesions of the gut may be very extensive; that the vital forces are at the lowest ebb. No one yet has hesitated to perform tracheotomy in the laryngeal complications of enteric fever, which require it to save life, for these reasons. The operative treatment of purulent peritonitis has been performed many times successfully by the gynæcologist in conditions scarcely less unpromising. In point of fact, the objections that may be urged against laparotomy in intestinal perforation in enteric fever are no more forcible than those which would have been made use of at first against the same operation in gunshot-wounds of the abdomen.

Unfortunately, this question is not to be settled by experiments upon animals. The investigation must be made upon the human subject. The courage to perform it will come of the knowledge that the only alternative is the patient's death. Certainly *a priori* reasoning will not help us. We must not, however, overlook the fact that while a few cases of perforation occur in the second week of the disease, while the infective process has yet some time to run, a far larger proportion take place in the period of convalescence, when the condition of the patient, except for a deep ulceration often single, is tending towards recovery.

DESTRUCTION OF NIGHT-SOIL AND GARBAGE BY FIRE.*

BY GEORGE BAIRD, M.D.,

Wheeling, West Virginia.

TO provide an efficient way of disposing of the night-soil and garbage of cities and towns has been a subject of much thought on the part of sanitarians for many years. Convinced that special contagious and infectious diseases are propagated, and that many diseases are disseminated, by pollution of the air and drinking-water, their energies have been directed to the providing of a plan for thoroughly protecting cities from the dangers resulting therefrom. With others, our health authorities for several years have been trying to devise a plan for so disposing of these substances as to protect our own people as well as the citizens of Bellaire, Ohio.

To make this understood, and at the same time furnish an example of the folly of claiming, as some do, that a running stream of water will purify itself in a few score feet, let us here give the relative situation of the two cities.

Wheeling is located on a narrow plain on the east side of the Ohio River, in West Virginia. This plain is bounded on the east by high hills, and on the west by the river. The city extends along the river for five miles. Opposite the extreme southern limit of Wheeling, on the west side of the river, is the northern limit of Bellaire, and that city extends for two miles down the river. About one-half mile from the north end of Bellaire her waterworks are located on the river-bank, and the supply-pipe extends out into the river one hundred feet from the shore at low-water mark. The current in the river is deflected by a bend, commencing a short distance above the southern line of our city, towards the Ohio or Bellaire shore, and substances thrown into the river at Forty-eighth Street—our last street south—are carried over towards the Bellaire side. Especially is this the case during low water in summer.

By one of our ordinances, night-soil men are required to haul all night-soil to Forty-eighth Street, and, after driving as far as possible out into the river, empty the contents of their carts and barrels. The garbage-collectors also empty their garbage into the river at various places along the river-front. From these two practices it results that the drinking-water of Bellaire is abominably polluted, and that city is made a hotbed of disease. In fact, it has the reputation of being the most unhealthy place in Eastern Ohio. For how much of this our city is responsible it is fearful to think; but that a great part of it is due to our way of disposing of the city's refuse matters there can be no doubt.

The furnishing of night-soil to gardeners as a fertilizer has been tried; also the giving of the garbage to dairymen. These plans have resulted in polluted wells and diseased cows. The loading of boats and towing them down below Bellaire has been suggested, and created such great dissatisfaction in towns situated farther down the river that it had to be abandoned.

Determined to relieve our own city of some of the causes of preventable diseases, which were too prevalent among our people, and at the same time relieve her of the injustice she was almost daily doing to her neighbor below, our health department last spring made a series of experiments in the destruction of night-soil and garbage by fire, and we claim that at last we have secured a means of entirely destroying these substances and their power to do evil. The experiments had to be made between late bedtime and morning, as a great prejudice existed in the people's minds to having night-soil burned near their residences.

Two facts about the burning of night-soil specially impressed us: one was that the odor was not such a one as we all

* Read before the American Public Health Association at Toronto, Canada, October 5, 1886.

thought it would be,—it was something akin to the smell of burnt leather; another was the intense heat required to burn it.

The first experiments were made in a bench of five retorts at our city gas-works. The night-soil was mixed with fifty per cent. of fine slack, and three retorts were charged with this mixture. The other two retorts were charged with a mixture of equal parts of night-soil and "breeze,"—fine coke siftings. The reason for adding these substances was to divide the night-soil and provide an inflammable substance within its mass to assist in burning it. The retorts were charged at 11 P.M., and it was not until seven o'clock next morning that the contents were reduced to a fine odorless powder. On another occasion, three retorts were charged with a mixture of twenty per cent. of fine coke and eighty per cent. of night-soil, and two with night-soil alone. The result was the same as before with the mixed charge: nine hours were required to burn the unmixed.

Convinced that the retorts were not the proper things for successful combustion of this substance, owing to the want of a free supply of oxygen, it was determined to find a furnace with a strong draught, capable of producing a greater heat than could be obtained in the retorts.

Fortunately, a change made shortly before this time in the process of making nails in our mills provided what was desired. The change from the iron to the steel nail had dispensed with the boiling-furnace, and on application being made to Mr. Reister, manager of one of our iron-mills, for the use of one of these furnaces, the privilege was cheerfully granted, and by his order it was prepared for the third experiment. After twenty-four hours' heating, a charge of twenty per cent. fine slack and eighty per cent. night-soil was made, and it was burned in one hour and twenty minutes. A second charge of "breeze" and night-soil was made, and it was burned in little more than one hour. A third charge of night-soil alone was made, and it was burned in about the same time as the first charge.

Another change in the mills arising from the introduction of the steel nail was the building of the Smith gas-furnace for the heating of the steel slabs preparatory to being rolled into nail-plate. This furnace is much larger than the boiling-furnace, and capable of generating a more intense heat than any furnace known. Application was made for the use of one of these furnaces, and it was kindly granted. The result of this experiment was as follows: a barrel of ordinary garbage, or slop, was burned in four minutes; a barrel of butcher's offal (bones and animal matter) was burned in seven minutes; a barrel of fluid night-soil (thrown into the furnace with buckets) was almost instantly evaporated; and a barrel of solid fæces was burned in fifteen minutes.

Convinced that this furnace had every requisite for fulfilling the design of destroying night-soil and garbage, the Committee on Health reported the result of the above experiments to Council, and recommended the making of a contract with Mr. Smith for the building of a furnace capable of destroying daily sixty tons of night-soil and garbage, and also for burning dead animals of all kinds which might die within the city limits, as well as the refuse matter from our butcher-shops. This furnace is to be constructed for using natural gas as a fuel. Of its success there can be no doubt.

The heating capacity of natural gas is more than four times as great as that of coal. With coal, we destroyed night-soil in a boiling-furnace in one and one-quarter hours; with artificial gas, generated from fine slack, we burned it in fifteen minutes; with natural gas we can do still better. Notwithstanding the great difficulty in destroying this substance by fire, there is in the use of natural gas as a fuel more risk of destroying the furnace than of not entirely consuming the night-soil.

It must not be understood that this furnace can only be used in cities and towns where natural gas has been introduced as a fuel. Mr. Smith has gas-generators built with his furnaces in cities where there is no natural gas, and claims that he can "produce a heat of greater intensity and with more economy than by any other method or from any other source outside of natural gas, and as cheap as natural gas can be supplied by a private company."

The fine coal, or slack, is not the only substance from which artificial gas can be generated. Tan-bark, peat, and many other substances can be used. It is much regretted by us that this furnace will not be completed before the meeting of the Public Health Association in October. It would be a great satisfaction to be able to

report its successful workings to this body. Mr. Smith's faith in its success is so strong that he has agreed with our city to ask no compensation until by a series of successful experiments he has shown its capacity to destroy all substances proper to be offered as tests of its powers.

Should any member of the Public Health Association feel sufficient interest in the subject of the destruction of city refuse by fire to wish to obtain more information in reference to the Smith furnace, if he will address M. V. Smith, M. E. Bissell's Block, Pittsburg, Pennsylvania, he will be furnished full details. Mr. Smith being the inventor and patentee of the furnace, we do not feel at liberty to attempt a description of his furnace, and have only tried to furnish proof of its capacity to solve a long-tried problem in the government of our cities and large towns.

ECHINOCOCCUS OF THE LIVER.

BY CHARLES BAUER, M.D.,

Late Chief Assistant Physician to the Out-Patient Department of the Hospital of the Jefferson Medical College.

SO few cases of hydatids of the liver are reported in our journals that it may not be uninteresting to report one which came under my observation while physician to the Out-Patient Department of the Hospital of the Jefferson Medical College.

The patient, I. Z., a German, came to the hospital November 23, 1885, and gave the following history:

He was 35 years old, married, a shoemaker by occupation, and had come to this country in 1881. He had been and was then in good general health, with no history of inherited or specific disease. Three months later his wife noticed a slight prominence upon the right side of his chest, below the nipple. This gradually increased in size, causing no pain, for nearly a year and a half, when he became jaundiced and experienced a feeling of weight and dragging in the right hypochondrium, shortness of breath, and slight cough. Consulting a physician, he was told that he had enlargement of the liver. The treatment instituted had no effect upon the steadily increasing tumor; his appetite failed, he began to lose flesh, and he became progressively anæmic.

Examination now revealed an enormously distended abdomen, the liver-dulness extending from the second rib to a little below the umbilicus, and transversely to within half an inch of anterior border of the spleen. The outline of the mass was irregular, and the lower portion nodulated. Abdominal veins were enlarged (caput Medusæ). There was œdema of legs extending to the thighs, with pitting on pressure. Spleen enlarged. Both sounds of the heart were distinct, but the first was short and valvular and lacking in power. The area of cardiac dulness was not increased.

The patient looked pale. He stated that he had lost considerable flesh. His appetite at the time was fair, and digestion tolerably good. He had never vomited nor passed blood by stool. After exertion he had much dyspnœa, and he also had a slight cough.

Urine was of sp. gr. 1020, rather dark, feebly acid, and contained albumen and casts. These, examined under the microscope, were found to take the amyloid stain.

Notwithstanding the character of the tube-casts and the enlargement of spleen, usually considered characteristic of amyloid disease, and in spite of the fact that the tumor appeared irregular and nodulated and that the man had lost considerable flesh (conditions that would point to carcinoma), I was led to make the diagnosis of hydatid disease for the following reasons: the patient's age; the almost painless growth of the tumor; the comparative absence of constitutional disturbance during eighteen months from the time it was first observed; the duration of the case, and from a personal observation of the man's surroundings, which were of the most humble character. He with his family occupied two rooms, one used as a bedroom, the other serving as kitchen, sitting- and dining-room, and workshop. Like most poor people, they kept dogs and cats, which, as I afterwards ascertained, often shared the bed with them. Food and water were left about the room in a most careless manner.

The patient was ordered thirty-drop doses of the syrup of the iodide of iron thrice daily, which seemed to improve his condition so markedly that the correctness of my diagnosis was much questioned. Four months later I was called to his house (he had taken no medicine for six weeks). He complained of severe pain in his right side; his legs were greatly swollen; his breathing was difficult; the heart's action disturbed and feeble; and there was anorexia and scanty micturition. His temperature was 99.4°. I gave him a hypodermic injection of one-fourth of a grain of morphine with $\frac{1}{120}$ of atropine, to relieve pain, and ordered him infusion of

digitalis with acetate of potassium in elixir of cinchona. Evening doses of one-fourth grain of morphine were necessary to relieve pain and secure rest. In about five days (during which his temperature was normal) he was so far better that I desired him to come to the hospital again for further treatment. At his next visit I determined to puncture the tumor with a long hypodermic needle, to obtain, if possible, some of the fluid found in hydatid cysts. Fortunately, Drs. Allis and Longstreth were present. The characteristic "purring tremor" was distinctly elicited by palpation. Some fluid was also obtained, but failed to show any hooklets or tæniæ under the microscope. The puncture gave rise to considerable pain, and the patient remained in the hospital from April 26 until May 4, 1886, during which time several unsuccessful attempts to aspirate the cyst were made.

A few days after leaving the hospital he sent for me again: he was then suffering with localized peritonitis, and I continued to attend him until his death from exhaustion, which occurred June 25 of this year, nearly four years after the tumor was first noticed.

Pathological Report.—The post-mortem examination was made by Dr. Rively about twenty-four hours after death. Cadaveric rigidity was present; emaciation not very marked; œdema of lower extremities with ascites was observed. On section we found but little fat. The abdominal veins seemed dilated.

The right lung presented old adhesions at the apex posteriorly. The adjacent pleural surfaces of the left lung were firmly adherent. The right lung was much compressed by the enlarged liver extending up to the second rib.

The pericardium contained about one ounce of fluid. The left side of heart fully contracted. There was fluid blood and a recent clot in right ventricle. The valves seemed normal.

Spleen much enlarged, weighing thirteen ounces. Kidneys, with the exception that the left seemed somewhat larger than usual, exhibited nothing abnormal.

The liver extended to second rib on the right side; its upper portion smooth, but its lower nodulated. The upper part of the right side was adherent posteriorly, and also adherent to the diaphragm. The gall-bladder contained fluid.

From the upper surface of the right lobe of the liver the large cyst projected. The weight of the liver before rupture of the cyst was fifteen pounds six ounces. Upon evacuation, the cyst was found to contain one hundred and forty-eight ounces of a clear, opalescent, slightly alkaline fluid, of the specific gravity of 1008, with no trace of albumen. Within the great cyst was a small one about the size of a marble. Upon submitting the fluid to microscopical examination we found it to contain the tænia echinococcus and hooklets in large numbers. We also examined microscopically a section taken from the substance of the liver, and found the fibrous tissue between the lobules thickened and increased. This increase of fibrous tissue explains the nodulated condition of the liver, a certain amount of interstitial hepatitis having taken place.

1949 N. Thirteenth Street, Philadelphia.

THE USE OF DIGITALIS IN COMBINATION WITH BROMIDES IN EPILEPSY.

BY GEORGE A. WIGGINS, M.D., L.M.

COGNIZANT as we are of the enormous extent of the literature already in existence, almost the first impulse would be to say that the subject of epilepsy had been exhausted; but, on the contrary, it seems as if the more we read of it the more interesting it becomes.

Herewith I submit for consideration the history of two cases and their treatment, which I think are sufficiently interesting to be placed upon record.

Case I.—Mrs. W., Dublin, Ireland, aged 38 years, a widow, the mother of five children, the youngest of whom was nine years of age. Patient was anæmic and emaciated, though formerly robust and healthy. Family history did not indicate epilepsy, insanity, or any other nervous disease, and the suspicion of syphilitic infection was entirely out of the question. Some months after the birth of her youngest child she was seized with epileptic fits, which were very severe and of frequent occurrence. She was attended by four eminent physicians of the city of Dublin with indifferent success, excepting one, who succeeded in checking their frequent occurrence; but still they occurred in decreased numbers until December, 1883.

I first saw her at this time, in a genuine convulsion, after she had fallen down-stairs

and defaced her countenance to a great extent; her tongue was greatly mangled, and "was much inflamed and swollen for some days after." The mouth was foaming vigorously, the face was very much convulsed and contorted, and the limbs worked violently. Consciousness was delayed for a lengthened period. When consciousness did return, I gave her fifteen grains each of potass. brom. and hydrate of chloral, which seemed to have no beneficial effect, the patient being extremely restless and nervous all the night.

Next morning I gave her the following prescription:

℞ Potassii iodidi, ʒj;
Potassii bromidi, ʒj;
Ammonii bromidi, ʒiiss;
Potassii bicarbonatis, ℈ij;
Spiritus chloroformi, fʒij;
Infusi digitalis, q. s. ad fʒvj. M.

Fiat mist. Sig.—Take two teaspoonfuls morning and noon, and three at bedtime.

After one week she took only one teaspoonful morning and noon, and three at bedtime.

The patient recovered completely, never having another fit; but in the beginning of her treatment she had some tendency to have them by the occurrence of the aura in one or other of her arms. These, however, were presumably prevented by tightly bandaging the arm with a handkerchief when this valuable precursor manifested itself.

Case II.—Master T., a boy of 15 years, from Plainfield, New Jersey. He was so large, plethoric, and healthy-looking that he seemed developed altogether out of proportion to his age. As in the first case, the family history as far as I could ascertain was altogether free from any diathetic taint. The mother told me she was only trying my professional skill as an experiment; human aid in the case was impossible, she thought, as already she had engaged the services of several physicians and numerous quacks, from the Indian medicine-man down to the faith-cure. The boy had an enormous appetite, and, having an indulgent father and mother, he was allowed to eat very irregularly, and in fact gluttonously. (This, by the way, was always a very good platform for the quacks, for they invariably cried "Worms!" when they heard of his eating capacity.) His bowels were costive, as might be expected from his gormandizing. The fits were congenital, and had occurred very frequently in this case; so much so that the mother could hardly ever trust him out of her supervision. She told me that he had, as the rule, from three to six fits daily, and occasionally as many as a dozen in the twenty-four hours.

I put him on the same prescription as the first case, with the following as a tonic laxative for his bowels:

℞ Extractæ cascaræ sagradæ fl., fʒiij;
Tincturæ nucis vomicæ, fʒiss;
Aquæ, q. s. ad fʒij. M.

Fiat mist. Sig.—Take one teaspoonful after each meal.

The boy got perfectly well, his recovery dating from the second day of his taking the medicine, he having had one the day before.

In conclusion, here seem to be two cases of opposite conditions,—the one anæmic, the other plethoric.

The question is naturally asked, "To what was the cure due?" "Undoubtedly," some might say, "to Brown-Séquard's prescription,—which it really is, except that the infusion of digitalis is substituted for infusion of columbo." To this I must answer "No," as I happened to ask Dr. Nicolls afterwards what his treatment had been in the first case, and he told me it was Brown-Séquard's mixture exactly. In the second case bromides had been prescribed *ad libitum*, but the number of fits remained the same except when the drug was pushed to its full physiological action.

What I particularly wish to have noticed is the treatment of epilepsy with digitalis. This treatment is not original, as Sir Dominic Corrigan, Bart., used it in Dublin with very great success, although he preferred the powder. The effect produced on delirium tremens by large doses of digitalis, demonstrated by Jones, is truly wonderful, and proves it to be a most potent sedative in some conditions of the nervous system.

Probably digitalis, in conjunction with Brown-Séquard's prescription, is worthy of careful consideration and trial in a disease which sometimes requires all our resources to control.

Surgical Institute, Philadelphia.

Death due to Hemorrhages caused by Foreign Body in the Bronchi.—Dr. Axel Key reports (*Hygeia*) the case of a man, 36 years of age, who died with pulmonary hemorrhage, to which he had been subject for seventeen years. Upon section, six pine leaves, stiff and with sharp points, were found projecting from the mucous membrane of a dilatation of a bronchus in the left lung. The embedding of the leaves in the lung had led, in the opinion of Dr. Key, to the hemorrhages and fatal result.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF WILLIAM OSLER, M.D.,

Professor of Clinical Medicine.

(Reported by WILLIAM H. MORRISON, M.D.)

CLINICAL REMARKS UPON A CASE OF ANEURISM OF THE ARCH OF THE AORTA.

GENTLEMEN,—The case which I shall demonstrate this morning is one which I have just seen for the first time, but it is one in which the diagnosis can be made upon a very superficial inspection. For the past twenty years this man has been working as a cabinet-maker; previously he had been a shoemaker. He has never had any sickness, with the exception of chills and fever, which he had when twenty-one years old. He has never had rheumatism or syphilis. He noticed the first signs of the present affection six years ago, when he had a trouble with the heart which he describes as a feeling of beating and jarring when he lay down. He did not have shortness of breath, and was able to continue his work. About two years ago he had a sharp pain to the right of the sternum. His principal complaints now are shortness of breath and nervousness, with occasional pain over the upper part of the right chest.

He presents a healthy appearance, and is young-looking for his age,—46. The vessels of the face, especially the veins, swell rapidly on exertion. If he walks a short distance the face flushes. The pupils are of medium size and equal. There is no difference in the color of the sides of the face. The vessels of the neck are not specially full, although the external jugular veins are evident; there is no special throbbing in the neck; there is a little increased fulness below the right sterno-mastoid muscle. There are several distinct superficial veins crossing the sterno-clavicular articulation.

Inspection shows a fairly well developed thorax; expansion slight and chiefly in the lower costal region. There is marked dilatation of the venules about the costal margin, particularly at the ensiform cartilage. A few of these venules are noticeable on each side of the sternum. The apex-beat of the heart is visible about one inch below and two inches outside of the line of the nipple; the beat is forcible; the cardiac impulse is also noticed in the angle between the costal margin and the ensiform cartilage. What attracts particular attention is a hemispherical prominence on the right side of the chest, immediately below the first rib.

Upon careful inspection of this a slight heaving pulsation is seen, but it is not very noticeable. It is difficult to determine by inspection whether or not this pulsation is synchronous with that of the apex-beat.

Upon palpation, the pulsation is very distinct and expansile. In this manner I determine that its rhythm is systolic. There is no distinct interval between the cardiac impulse and the pulsation of the mass. The sensation communicated to the hand is that of a firm, solid body. The tumor evidently projects through the ribs and costal cartilage. Its limits can be accurately fixed by palpation; it extends from the first rib above to the third rib below. A portion of the third rib and its cartilage can be distinctly felt; the second cannot be felt. Laterally it extends to the right edge of the sternum, not involving the bone directly. Its outer limit can be fixed with great distinctness; its edge is very sharply defined. At present the swelling does not appear to be painful, although the patient states that there has been considerable tenderness at times. As I have said, there is communicated to the hand a distinct impulse, systolic in time. Following this is a diastolic shock, and with it a very slight tremor or thrill.

Upon percussion, there is dulness over the whole region of the tumor, and extending over the left half of the median portion of the sternum, but not involving the manubrium; its lower limit merges into the cardiac dulness.

Upon auscultation, there can be heard a very distinct long blowing sound or murmur occurring at the same time as the pulsation, and following it is the flapping second sound. As the heart is approached the systolic murmur becomes more distinct, and at the third left costal cartilage there is heard a second murmur, diastolic in time and very distinct in the mid-sternal region and towards the ensiform cartilage. As we have already noted, the apex-beat is very much dislocated from its normal position. It is felt in the sixth intercostal space, at least two inches outside of the nipple-line. Auscultation of the heart shows a systolic murmur heard best at the apex, but not

transmitted into the axilla. The pulse is quiet, at present 92 in the minute. Comparing the pulse in the two radial arteries, that in the left seems fuller and more distinct than that in the right. This is still more evident when the brachial arteries are compared. Auscultation of the lungs posteriorly shows no apparent difference in the respiratory murmur of the two sides. On attentive auscultation there can be heard in the right scapular region a murmur which is doubtless transmitted from the tumor.

The nature of this malady is evident. The man has an aneurism of the aorta. The diagnosis in this case is unusually easy: you cannot always with such positiveness assert that you are dealing with aneurism. When, however, there is a tumor projecting to the extent that this does, with this peculiar expansile pulsation, it is almost certainly an aneurism. If we divide the arch of the aorta into its three portions,—the ascending, transverse, and descending portions,—it will be found that in the majority of cases the aneurism springs from the ascending portion: that is, between the aortic orifice and a point a little to the right of the origin of the innominate artery. This is the position which the aneurism occupies in this case. The ascending portion of the vessel is most prone to atheroma; and this explains why it is that aneurism is so common in this situation. Aneurisms involving this part of the vessel project anteriorly and to the right, in the direction of least resistance. The vessel having more room to expand, we find here the largest aneurisms. The most important structures in contact with the ascending portion of the arch of the aorta are the pulmonary artery and superior vena cava; the latter is particularly liable to be pressed upon, but we rarely see such serious effects of pressure here as we do in aneurisms affecting the transverse or descending portions of the arch. In this instance the aneurism has eroded the second rib and caused its entire absorption. Separating the sac from the outside there is simply the skin, and numerous firm, hard coagula which line the sac and obviate to a certain extent the effects of the blood-pressure.

The chief symptoms from which the man now suffers are shortness of breath and occasional pain. At present the pain is not at all severe, but he states that a few months ago the pain and tenderness were excessive. This was due to the erosion of the ribs, and it is very marked when an aneurism projects still more posteriorly and erodes the vertebræ. After the bone has become absorbed and the aneurism is in contact with the skin, as in this instance, the pain may be materially diminished. Pressure upon the nerves in the neighborhood of the heart may produce attacks of agonizing pain resembling angina, and in many cases it passes down the arms and along the cervical nerves. The dyspnœa at present is not noticeable when he is quiet, but when he moves rapidly or goes up-stairs there is shortness of breath and cardiac distress. This is due in part, I think, to the existing valvular disease, as the loud diastolic murmur down the sternum indicates that the valves are not competent.

Curative treatment is almost out of the question in an internal aneurism when it has reached such a size as this one. Occasionally, by the introduction of horsehair or a large coil of copper wire, or by electrolysis, the contents of the sac have been solidified and cure has been effected. Such treatment, however, is, I think, out of the question where the tumor is already so near the surface.

The treatment of such a case resolves itself into a matter first of rest, secondly of diet, and thirdly of the administration of one or two medicines which have been found of service. Rest is unquestionably the most important element in the treatment of internal aneurism. The pulse, which is one hundred per minute while the patient is sitting up, will be reduced fifteen or twenty beats when he assumes the recumbent position. Any one can calculate the number of pulsations saved in twenty-four hours. The sac will thus be directly spared many thousands of pulsations. It is this that makes rest so important in the treatment of internal aneurisms. Rest will reduce the pressure within the sac to a greater extent than could possibly be done by any medicine or arterial sedative.

The next point is with reference to the diet. One of the most successful methods of treatment of aneurism ever employed is that by restriction of the diet. This was introduced by Valsalva, and modified by Tuffnell, of Dublin, who placed his patients upon a diet consisting of not more than eight ounces of solids and ten ounces of liquids in the twenty-four hours.

A couple of ounces of solid food with milk or tea were given in the morning, a larger quantity in the middle of the day, and a couple of ounces again in the evening. The restriction of fluids is particularly important. This unquestionably reduces the quantity of blood in circulation, and has an important bearing in diminishing the blood-pressure.

Of medicines, iodide of potassium is the only one which in my experience has proved at all efficacious in the treatment of aneurism. The relief is usually evident in two special directions,—relief of pain and reduction of the pulsations. Undoubtedly, under the use of iodide of potassium in fifteen-, twenty-, or thirty-grain doses three times a day, the pain is greatly relieved, and may disappear altogether. The pulsation becomes less forcible, and the sac may get much harder. The pulsation in this case has been greater than it is at present, and for some time he has been taking iodide of potassium in fifteen-grain doses.

There is an interesting etiological question in connection with this case. This man is a carpenter by occupation, and it has been noted that the workers in certain trades are particularly subject to arterial and cardiac affections. Carpenters are more liable to such diseases than are other artisans, with the exception perhaps of blacksmiths. In this instance the occupation may have had something to do with the production of the condition. The constant use of the arms brings a great strain upon the aorta, and may induce atheroma, which, in the great majority of cases, is the precursor of aneurism. Of other causes, syphilis is unquestionably the most frequent. There is no reason to think that this man has had syphilis. Rheumatism and gout also frequently attend arterial diseases, but in this case there is no history of such affections.

The prognosis is, of course, very grave. Cases of thoracic aneurism usually terminate within two years; but in the situation which this occupies, owing largely to the fact that no important structures are compressed, an aneurism may persist for many years and the patient enjoy a tolerably comfortable existence. Rupture into the pleura is a common mode of termination in these cases. The sac becomes thin, a little rent takes place, with effusion of blood and sudden death. Compression of the superior vena cava may lead to extreme congestion of the brain and to clotting in the sinuses, which proves fatal. Occasionally the aneurismal sac ruptures externally, and may bleed for some time before the fatal result takes place. I have seen an instance of large protruding aneurism in this region in which the patient wore with much relief a soft elastic strapping; but in this case the slightest pressure seems to worry him, and it would here do more harm than good.

CIRRHOSIS OF THE LIVER WITH FATTY DEGENERATION AND ENLARGEMENT OF THE ORGAN.

I wish briefly to refer to this liver, which was removed from a patient who died in the hospital the day before yesterday. The condensed notes of the case are as follows. T. E., a married woman, the wife of a saloon-keeper, was admitted to the hospital eight days ago, with dropsy and jaundice. She had used both whiskey and beer to excess. She stated that her present illness was of only three weeks' duration, and that it had begun with swelling of the abdomen and feet. She also complained of a cough, which had been present for a couple of months. Examination on admission showed the patient to be weak and anæmic; the eyes were jaundiced, and the skin presented a slightly yellow tint; there was great shortness of breath. The abdomen was distended, measuring thirty inches in circumference, and the umbilicus protruded. The veins over the surface of the abdomen were slightly enlarged. The liver-dulness extended in the nipple-line from the upper border of the fourth rib to one and one-half inches below the costal margin. The left lobe extended at least two and one-half inches below the ensiform cartilage. There was also slight enlargement of the spleen. Diarrhœa was present, and the temperature was elevated one or two degrees. Signs of congestion were present over the posterior part of both lungs posteriorly. The pulse was very rapid, and at night there was delirium. The patient evidently was failing rapidly, and, in order to relieve the oppression of breathing, about eighty ounces of fluid were removed, with apparent relief. She, however, continued to sink, and, as I have said, died the day before yesterday.

I wish to call your attention to the liver, which, as you see, is large and of a yellow

color, the color being largely due to the presence of fat. Upon the surface the organ is slightly rough and granular. To the touch it is firm and hard. The finger-nail can scarcely be forced into its substance. In the normal liver this can be readily done. On making a section of the organ, we find that it cuts with great resistance. The lobules show three distinct zones: first, a central region of a brownish color; secondly, a yellowish zone; and, thirdly, an outer zone of a grayish, translucent appearance, separating the lobules. On careful inspection, it is evident that the liver is the seat of extensive fibroid change. The lobules are surrounded with a new growth of connective tissue, which in places is quite marked, having in some portions completely destroyed the lobules. I call particular attention to this specimen because it is an instance of cirrhosis with enlargement, the increase in volume being due in great part to the fatty change. Fatty cirrhosis has been designated as a special variety by French writers, but the advisability of such classification is, I think, doubtful. It is not at all uncommon.

An interesting point in the clinical history is the sudden onset of the dropsy. Three weeks before her death this woman was in her usual state of health. In cirrhosis of the liver it is not common to have the fatal termination follow so rapidly the appearance of the first serious symptom, particularly if this is ascites. Hæmatemesis, however, may carry off a patient with great suddenness and be the first manifestation of the disease.

JEFFERSON MEDICAL COLLEGE.

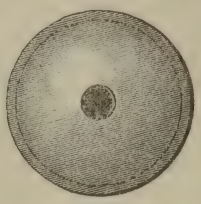
SERVICE OF JOSEPH HEARN, M.D.,

One of the Attending Surgeons to the Hospital of the Jefferson Medical College.

(Reported by W. M. Late Coplin, Resident Physician.)

TWO CASES OF IMPACTION OF TOY WHISTLES IN THE ŒSOPHAGUS.

BY reference to the accompanying cut (made the actual size), an idea may be formed of a toy likely to prove a rival to the toy pistol and similar inventions for the destruction of children. This apparently innocent toy is held between the lips and teeth, and apparently much amusement wrung from it by its boyish possessor by the noise made by blowing through it. The child carelessly carries the whistle in his mouth as he runs about, and upon making some sudden exclamation the toy drops back and falls into the œsophagus, where it lodges. Two cases have recently presented themselves at the Jefferson Hospital which may be of interest.



In the first case the child was 4 years old; had been playing with the toy, and as a result swallowed it. The usual symptoms of obstruction in the œsophagus supervened, and the little patient was brought to the out-patient department for examination. An anæsthetic was administered in order perfectly to relax the parts, and the surgeon, Dr. Hearn, passed into the œsophagus a bucket-probang or coin-catcher, forcing it gently past the foreign body, then, slowly withdrawing, brought up the whistle, which had been caught by the firm contraction of the œsophagus.

The second case did not differ materially from the first, the whistle being in each instance exactly similar to the one shown in the cut. In both cases the child was held in the lap of an assistant, its jaws held firmly apart by an instrument for the purpose, and in neither case did the manipulation extend over a period longer than five minutes. Dr. Hearn considers the bucket-probang or coin-catcher one of the most valuable instruments we possess for the removal of foreign bodies from the œsophagus.

An interesting point in connection with these cases is that they both occurred in the practice of one surgeon within the same week.

TRANSLATIONS.

Morbid Anatomy of Hysteria.—In the course of remarks upon the normal and pathological anatomy of the nerve-centres, at the Académie de Médecine, M. Luys directed attention to a specimen of a brain taken from an hysterical subject. He demonstrated anatomical peculiarities in this brain which had hitherto not been noticed. The morphological irregularity ex-

isted principally in the left hemisphere, where, at the level of the upper part of the fissure of Rolando, there was an abnormality which he himself had never seen before, consisting of a supplementary convolution coming from the centrum ovale and interjected between the extremity of the ascending parietal (which it pushed backward) and that of the ascending frontal (which it pushed forward). In the same lobe there was observed a decided thickening at the base of the ascending parietal, with multiple flexuosities. The right hemisphere was not similarly invaded, but the ascending frontal appeared broken in its continuity, forming a rare condition, such as is usually to be found in cases of chronic mania with hallucinations. Besides other features of secondary importance, he remarked the condition of extreme development of the quadrate lobes of each side. As some authors regard these regions as the proper territories of sensibility and psychic emotivity, this fact is important to note, as well as the projection of the paracentral regions, which also coincides with certain forms of cerebral excitation of which M. Luys had encountered several interesting examples.

He observed, in concluding his paper, that "it is seen, therefore, by this plain fact, that if hysteria is to be considered as a protean combination of original dynamic disorders, these dynamic symptoms alone do not constitute the disease. They reveal an underlying organic disorder,—a cerebral condition which is often inherited and fatally inherent to the subject, and which is the real characteristic of the bent of his mind and of the nervous manifestations of all sorts that it presents in its evolution, and which he cannot prevent. He is born hysterical, he lives hysterical, and he dies hysterical." The autopsies which he had made upon this subject at La Salpêtrière did not admit of doubt upon the subject in his mind.—*La France Médicale*, No. 116.

The Gastric Juice in Acute Phosphorus-Poisoning and in Pyrexia.—As the result of some experiments upon the gastric juice, Drs. Cahn and Von Mering declare that "the most severe diseases of the stomach are not capable of causing the disappearance of hydrochloric acid from the gastric juice." It appears that the formation of this acid is one of the most persistent functions of the organism. Phosphorus causes such marked degeneration of the mucous membrane and of the peptic glands that Dr. Cahn was induced to make some examination of the gastric juice of dogs after death from phosphorus-poisoning in order to ascertain if this condition might not prove an exception. It was found that hydrochloric acid was still secreted in quantity sufficient for gastric digestion, in spite of the extensive degeneration of the walls of the stomach and glandular organs. Incidentally, an interesting fact was noted, that as one of the results of phosphorus-poisoning sarco-lactic acid appeared in the gastric juice, probably due to the increased acidity of the blood. So far as is known, phosphorus-poisoning is the only case in which any other acid than hydrochloric acid is secreted in the stomach. The author concludes, if the extensive degeneration caused by phosphorus-poisoning is not capable of making the hydrochloric acid disappear from the glandular secretion of the stomach, that the gradual and less marked changes which accompany fever are certainly not capable of doing so. The view expressed by Klebs—that the early and marked digestive disturbances which accompany all fever processes are due to the absence or diminution of the hydrochloric acid—must therefore be renounced.—*Zeitschrift für Physiologische Chemie*, Bd. x. H. 6.

Resorcin in Skin-Diseases.—Dr. Wiss (*Les Nouveaux Remèdes*), having experienced great relief in his own person, while suffering with eczema of the hands, from resorcin, has used it in a number of cases with marked advantage. He employs it in the following forms: (1) in powder associated with talc or rice (one part to ten); (2) in solution with oil of sweet almonds and olive oil (of each three grammes, resorcin one to two grammes), or with glycerin (twenty per cent.); and (3) as an ointment combined with vaseline (one or two parts to twenty).

To Remove Stains of Iodine from the Skin.—The sulphide of sodium, or sodium sulphydrate, in a ten- or twenty-per-cent. watery solution, applied upon a compress, will remove the stain of iodine, as well as allay its irritant action when excessive.

EDITORIAL.

RHEUMATISM AND RHEUMATOID AFFECTIONS.

THE indefiniteness of our conceptions concerning rheumatism was the theme of an interesting discourse by Professor Immermann at the recent meeting of the German Association of Naturalists and Physicians. Immermann regards the morbid process characterized by the classical phenomena of fever, articular inflammation, and peri- or endo-carditis as an infectious disease. A number of other less characteristic affections may be included under the adjective "rheumatic." Among these is acute endocarditis without joint-affections. In these cases a recurrence is sometimes accompanied by joint-inflammation, showing that the former attack was also rheumatic, although one of the most pathognomonic manifestations was absent. Acute sero-fibrinous pericarditis is also sometimes seen, in which, in spite of the absence of other symptoms, rheumatism may be diagnosticated. The presence of valvular lesions of the left heart in such cases, indicating preceding endocardial inflammation, is an almost certain evidence of the rheumatic nature of the attack.

Certain forms of what Immermann terms *masked rheumatism* may also be often recognized. One of the most frequent of these is neuralgia, most frequent in the trifacial and sciatic nerves. They may be accompanied or not by fever. They occur in persons who have previously suffered from classical rheumatic attacks, or are accompanied by endocarditis or followed by joint-inflammation.

A peculiar form of masked rheumatism is the *spastic*. Contraction or stiffness of muscles, especially of those in the area of distribution of the spinal accessory nerve, comes on suddenly, accompanied by fever and pain in the affected muscles. The stiffness of the neck-muscles may simulate an attack of cerebro-spinal meningitis. The absence of an epidemic of the latter disease and the prevalence of rheumatism at the time will help in making a diagnosis. Salicyl compounds and antipyrin are specific in their influence upon true rheumatism, and may be used as diagnostic aids, just as the iodides are sometimes relied upon to make a diagnosis of syphilis.

Gonorrhœal and scarlatinal joint-affections, purpura with joint-complications, the so-called *peliosis* or *purpura rheumatica*, the articular affections in individuals suffering from bronchiectasis, rheumatic tetanus, Landry's paralysis, acute anterior poliomyelitis of adults, sporadic acute polyneuritis, and beriberi, may be for the present classed as *rheumatoid* affections, in order to distinguish them from true rheumatism, from which they differ in clinical history as well as in treatment. The painful affections resulting from "taking cold" should be designated, as suggested by Erb, as "refrigeratory," and not as "rheumatic."

The adoption of Immermann's suggestions would tend to introduce some system in the application of the much-abused terms *rheumatism* and *rheumatic*. We think, however, that, even at present, his class of rheumatoid affections could be reduced in number.

BILLROTH ON MEDICAL EDUCATION.

GREAT perturbation has recently been caused among professional circles in the Austrian capital by a pamphlet of Prof. Billroth upon "Teaching and Study of the Medical Sciences." This is not

the first time that the distinguished Vienna surgeon has employed his pen in this field. Ten years ago his remarkable book, "Ueber das Lehren und Lernen der medicinischen Wissenschaften an den Universitäten der deutschen Nation, nebst allgemeinen Bemerkungen ueber Universitäten," attracted much attention, and by its outspoken criticism gave rise to not a few heartburnings. His later work seems to have created a still greater sensation than his former one. A cursory examination of some of the points touched upon will show that the attention the pamphlet has attracted is not undeserved. Billroth heads his first chapter "The Preparation for the Study of Medicine," and complains that the average German brain is lacking in capacity and training for quick assimilation and reproduction. This he ascribes to defective domestic education and consequent want of a proper sense of duty among the students. Hardly fifteen per cent. of the matriculants attend his lectures at the university. He concludes, therefore, that there is too much liberty allowed to students, and condemns the elective system now in vogue. It is worthy of note that Mr. James Russell Lowell took a similar position in regard to collegiate studies in his address at the recent Harvard celebration.

"Liberty of Teaching and of Study" is the heading of Billroth's second chapter. He thinks that the effects of this liberty have been an enormous increase of students, with diminished attendance on lectures, very ordinary examinations, uncultured physicians, lack of medical men in the country, and overcrowding of the large cities. These complaints do not sound unfamiliar to our American ears. Billroth proposes to diminish these evils by enforcing better attendance on lectures and clinics. Medical students are not competent of judging what degree of attention they should devote to the different branches. The Faculty must prescribe the studies and insist on compliance with their requirements. In our opinion a little more supervision would benefit students in American colleges as well as those of Vienna.

The Vienna medical school is overcrowded with students, which Billroth thinks is an evil. In this we quite agree, though we believe that American college professors count such an opinion a great heresy. In this country the largest class of students is supposed to indicate the best school,—which by no means follows. Billroth says that the quality of the teachers has but a slight effect upon the number of the students, but a great influence upon the acquirements of the latter. Good teachers and facilities for teaching, and few students, make good doctors. An increase in the number of medical schools in the Austrian empire is advocated, in order to relieve the great pressure on the Vienna university.

Billroth also pays his compliments in no very amiable way to the Faculties. The teachers are declared to be too numerous. At the Vienna school there are nineteen ordinary professors, forty-four extraordinary (or adjunct) professors, and sixty-five docents (tutors), a total of one hundred and twenty-eight. The same condition of things is becoming yearly more prominent in this country. It might be wise if our Faculties paid some heed to the warning of the great surgeon, whose profound study of the problems involved gives his opinions the force of authority.

THE CENTENNIAL CELEBRATION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

A COMMITTEE, consisting of Drs. Alfred Stillé, S. Weir Mitchell, I. Minis Hays, J. Ewing Mears, and S. W. Gross, has been for some time engaged in making preparations for an appropriate celebration of the centennial anniversary of the founding of the College of Physi-

cians of this city. The programme has been arranged as follows:

"1. An address by the President of the College will be given at Association Hall on Monday evening, January 3, 1887, at half-past seven o'clock.

"2. At nine o'clock on the same evening a Reception will be held in the College building. To the Address and the Reception invitations to ladies will be issued by the Committee on request of the Fellows.

"3. On Tuesday, at twelve noon, a meeting of the College will be held at which Honorary Fellowships will be conferred upon distinguished members of the profession.

"4. At half-past six, on Tuesday, the anniversary dinner will be given in the College building.

"5. A loan exhibition of the portraits of Fellows of the College, with those of distinguished members of the profession, will be held; and also

"6. A loan exhibition of rare medical books and rare objects of medical interest."

Fellows of the College are earnestly requested to make contributions of portraits, rare books, and objects of medical interest from their own collections; and their earnest co-operation is desired by the Committee, in order to make the celebration in every way worthy of the occasion.

The College was organized by a number of the representative physicians of Philadelphia on the 2d day of January, 1787, the object in view being "to advance the science of medicine, and thereby to lessen human misery, by investigating the diseases and remedies which are peculiar to our country; by observing the effects of different seasons, climates, and situations upon the human body; by recording the changes that are produced in disease by the progress of agriculture, arts, population, and manners; by searching for medicines in our woods, waters, and the bowels of the earth; by enlarging our avenues to knowledge from the discoveries and publications of foreign countries; by appointing stated times for literary intercourse and communications; and by cultivating order and uniformity in the practice of physick."

In view of the fact that the anniversary falls on the 2d day of January, Sunday, the conclusion of the address of Dr. John Redman, delivered at the meeting for organization, seems so especially appropriate that we make the extract from the original minutes:

"Respected Brethren,—After I had writ the preceding address, my mind took a more serious turn, which I willingly indulged. As the current of my thoughts related to the most substantial good of the Institution, and in a certain degree evidenced the earnestness of my desires to promote it.—Under that view, craving your indulgence a few minutes longer, I will venture to read them as they were hastily written, exactly according to their rise, progress and termination in my own mind; and though the manner in which they were expressed may not bear every kind of criticism; yet I trust the matter of them is such as will give offence to none, but be approved by you all. Especially as the principles and grounds of them are the words of one of the wisest of men: I mean King Solomon in his 3d Chapter of Proverbs, 'Trust in the Lord with all thine heart, and lean not to thy own understanding; In all thy ways acknowledge him, and he shall direct thy paths.' The antiquity of which words I hope will be no objection to them, with medical Gentlemen who acknowledge that some of their oldest authors are equal if not superior to many of the moderns. Be that as it may, They led me to consider That in one place of the Scriptures of truth it's declared (and believed by all who count them authentick and have made them the subject of their Rational attention and serious meditation)—That by the God of Heaven Kings Reign and princes decree Justice; and elsewhere 'That except the Lord build the House, they labour in vain that build it.' 'Except the Lord keep the City, the watchmen waiteth but in vain.'

"Taking these for granted, which I do most heartily, I am Convinced that it highly becomes rational men in all their lawful Enterprises and Undertakings of importance, Especially those which require Wisdom and Judgment, prudence and perseverance, effectually to accomplish them:—To acknowledge God to be their Sovereign Ruler and the Over Ruler of all Events, In Wisdom, Justice, goodness, and Truth; and also to acknowledge their obligations to him for every good they have or do enjoy; as well as their dependence upon him for any good which they still hope for or expect in the prosecution of their affairs publick or private, And for his protection, direction and success therein; and accordingly I invoke his aid, and implore his blessing thereon. Hence it is that I feel it both my duty and inclination, as your oldest member, and especially as your President, and as very becoming us at the Commencement of this our Institution, In your name and in your behalf, To acknowledge the Supreme Being to be our Sovereign Lord and Ruler; And also our obligations to him for every mercy and blessing we have been the subjects of, and especially for giving us capacities for such an Undertaking and Influencing our wills to engage in so good a design at this time. In same manner I

do also acknowledge our Dependence upon him for protection, direction, blessings and success herein: and furthermore I do also in your name and behalf, Invoke his Aid and implore him to grant unto us in this and all our lawfull enterprises, all that Wisdom, Prudence, discretion and Judgment, which are necessary to conduct it in a proper manner, to good effect and usefull purposes;—and also all that grace which may enable us to act herein from right principles, with just motives, to good ends, and according to the best rules and Regulations so that in this and all our works and ways we may glorify God, and do good in our days, and finally That after we have publickly and privately served our Generation faithfully, According to the will of God, we may be fitted for and admitted into his Kingdom and Glory, through Jesus Christ our Lord and Saviour."

The spirit of the founders of the College apparently is not shared by the Committee on the Anniversary Celebration, or such a rare opportunity of formally opening the ceremonies by a religious service on the natal day of the College would not have been so palpably slighted. At least two of the ex-presidents of the College lie buried in St. Peter's, one of the oldest churches of the city, and we learn that the Fellows of the College who wish to attend divine service at this church on the day named will be cordially welcomed. If it is desired by a number of the Fellows it is not yet too late to have this service entered as a part of the programme, and those who wish to attend can do so, and those who may not care for it can stay away.

The Association of Ex-Resident Physicians of the Pennsylvania Hospital will hold its second annual meeting in the Library of the Hospital December 16, 1886, when a dinner will be served and several interesting addresses made. A number of invited guests are expected to participate, among whom will be the venerable William G. Malin, who was the faithful steward of the Hospital for more than half a century. Dr. Thomas S. K. Morton is the Chairman of the Committee. Acceptances should be sent to the Hospital. A large attendance of the older Residents is especially desired.

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

Therapeutics in Paris.—It is rather surprising to an American medical student in Paris to find such a slight interest taken here in therapeutics, as he is accustomed at home to hear full details upon the subject. At the official lectures given by the Professors, about fifty-six minutes are usually taken up in giving the pathology of a disease, and in the few minutes of the hour remaining but little can be said on treatment in the individual case. It is the same at many of the hospitals. The attending physicians will expose the fine points of every case in a most learned manner; but when it comes to the medication they will often fail to say a word about it, leaving it all to the interne to do as he thinks best in regard to it. It must be admitted that there is a wide-spread distrust in Paris in regard to the therapeutic value of drugs.

Professor Hayem, who holds the chair of Therapeutics at the Faculty, is a very good physiologist; his well-known experiments on blood, circulation, etc., are wonderful in their way; but he does not attempt to deliver any set course of lectures on materia medica and therapeutics, and during his short spring term he can only touch on a few of the newer therapeutical agents. But it must not be supposed from this that the healing art is entirely neglected in Paris. Quite the contrary; for we have in the doctors attached to the hospitals a large number of excellent practitioners and teachers. There are no distinctions made among this class of medical men; they all have the same title of *Médecin des Hôpitaux*, and each one has charge of a certain number of wards. Among them are many who are not Professors, nor even *Professeurs agrégés* in the sense of having the legal title and being attached to the Faculty of Medicine; but their clinical lectures are even more generally followed than those of the Faculty. M. Péan, the well-known surgeon of the St. Louis Hospital, is one of these men, and in especial connection with our present subject of therapeutics we have M. Dujardin-Beaumetz, of the Cochin Hospital (who is often spoken of as Professor in the United States), one of our shining lights, and he gives every year a valuable series of lectures and experiments on modern medicine.

Another eminent teacher is Dr. Henri Huchard, physician to the Bichat Hospital, who also gives a course of lectures that is elevated in style and eminently interesting. He has had fitted up at the hospital a most convenient and complete therapeutical laboratory, with regard to which he recently publicly made the following statement: "I wish to announce that this laboratory of therapeuti-

cal research is free to all who may be interested in the work. They may have a seat at the desks, and make use of all the ancient and modern medicines in stock for purposes of study without expense. M. Paul Chéron has charge of the biological and chemical department, and M. Charles Eloy of the therapeutical and the pathological anatomy section, and they will both be glad to offer their advice and assistance in experimentation."

We take some extracts from notes of a volume of clinical lectures on medical therapeutics by Dr. Huchard, which will be issued by O. Doin, publisher, early in 1887. The doctor, in speaking of "General Therapeutical Indications," first details four cases of pneumonia in each of which he employed different medication, according to the indications. For one case bleeding was used, with injections of morphine; for another sulphate of quinine in large doses; for the third Todd's potion, with injections of caffeine and urethan; and for the fourth case he put in practice the celebrated answer of Magendie, "Did you ever try doing nothing?"—the expectant system, in fact. He very pertinently asks, "Why this difference in medication in the same disease, or the same morbid state at least? It is because in clinical medicine one should not treat a disease, but the patient; and there are no local maladies, but the malady is localized. Sydenham was right in saying, 'Practice of medicine consists more in knowing true indications than in inventing remedies to fill them.' What is an indication? '*Agendi insinuatio indicatio est*,' Galen said, and we define this to be the therapeutic deduction founded on an examination of the patient and his disease. It results from this that we should take into account the disease, the patient, and the remedy. For the first, search the cause, its lesions, its complications, etc.; for the patient, regard must be had for constitution, temperament, age, sex, physical strength, his surroundings, and especially the season of the year. As to the medicine itself, the question of dose is a most important one, as different effects can be obtained from the same drug according to the method in which it is administered and according to the quantities used. For instance, the cardiac action of digitalis can be obtained with quite small doses, but its antifebrile action is only demonstrated by comparatively large doses. For the modifying and restoring action of arsenic on nutrition it should be given in doses of not more than five milligrammes to one centigramme per day; but in chronic malarial poisoning the dose must be raised to two to five centigrammes in the same period of time. Sulphate of quinine in moderate doses is a most powerful anti-neuralgic remedy, but the dose must be massive in malarial fevers; and, again, it may fall to five or ten centigrammes when given in the continued dose to obtain its tonic properties. If morphine be injected in proper quantity, it procures calm sleep; but it is usually exciting in small doses. All these facts have an important practical use, and they impose the obligation of modifying doses according to the state of the patient and the therapeutic effect sought for."

We pass over some most interesting lessons of Dr. Huchard's and close with extracts from the section on "The Abuse of Medicine," where he gives some amusing details of the good old times in France. "Bouvard, one of the doctors of Louis XIII., gave him in one year two hundred and fifteen purgatives and two hundred and sixteen injections, and also bled him forty-seven times. History also tells us of the *Grand Monargue* that he was bled thirty-eight times from 1647 to 1715, and that he took two thousand purgatives, either of 'precaution or of urgency,' as they put it. Indeed, so much was the evacuation system in fashion then, that the Duke of Saint-Simon relates in his works that the Dauphiness had a clyster introduced by her chambermaid in presence of the king and the court. The famous case at law of those times of Boyau *vs.* Bourgeois, for payment of two thousand nine hundred and ten *lavements* administered in two years, is celebrated. Make the calculation, and see how many daily injections the unhappy fellow had to take. Well, these old-time exaggerations, which only excite a smile to-day, were made according to a theory, or a doctrine, and, even if times do change, the theorists remain unchangeable. There are also 'moral indications.' Chomel, a great and honest man, observed, 'In great physical, as well as in psychical, pain, sympathy is sweet to the afflicted, and that of the physician is above all precious.' The doctor, with a little tact, will associate himself closely with all the little trials of his patients, suffering with them as it were; which, after all, is not much of an effort for a man of heart. Called once to a patient in great pain, we asked why he had given up the services of a good doctor that we knew had been in attendance. 'Well, he said he could not cure me, and he did not even comfort me, as he did not *sympathize* with me.' The advice is given to try to treat patients as much with your heart as with your intelligence. Particularly is kindness useful in nervous diseases, for ever since man existed and suffered the language of pity has always been one of great use in relieving pain. A kind pressure of the hand or a charitable phrase often does more good than all the ingredients that we have boiled, filtered, or crushed in a mortar." Dr. Huchard finishes this part of his work with Trousseau's exclamation to the theorists, "For pity's sake, gentlemen, give us a little less science and a little more art," and he adopts as a profession of faith, "*Ars tota in indicationibus.*"

Treatment of Chronic Articular Rheuma-

tism by Passive Movements, notwithstanding the Pain.—Professor Trastour, of Nantes, has published an interesting article on this subject, of which we may give some details. Immobility of the joint affected in *acute* articular rheumatism is without question the proper treatment; but it is not the same in *chronic* forms. No matter if the bones, cartilages, ligaments, synovial structures, and muscles are all attacked, Dr. Trastour advises as the first and most important part of the treatment gradual movements with moderate continual exercise. He tells his patients to keep moving, notwithstanding the pain it causes: that is the price of cure. He has seen for the last seven years a series of most excellent results from this method. He was led to adopt the plan from observing that rheumatic patients in the wards who were made to move did not ever get so infirm as those who were permitted to remain in bed. If there is an inflammation in chronic rheumatism, which is disputed, it will certainly not go away, for this disease is progressive, and all the articulations will get it in time if it is allowed to go on. Infirmity increases and becomes incurable, and immobility leads to anchylosis.

Professor Massé, of Bordeaux, Professor Verneuil, and other surgeons recommend motion after the inflammation has been cured, but Dr. Trastour is of opinion that movement must be used at once in all chronic cases. Before applying motion notwithstanding the pain, be sure of your diagnosis of any of the so-called forms of chronic rheumatism (deforming, nodose, gouty, dry arthritis, etc.), because one might fall into an error at first; but if on examination of several joints more than one is found affected (as, for instance, the finger-joints with the knee), the treatment by motion may be recommended. The moment, in fact, that the disease seems to generalize itself, movement must be used. A number of cases were cited to prove the benefit derived. One of them is quite a striking case of a man who had progressed so far towards immobility, according to the rest-system, as to have his food cut up for him, and was afraid to move his hands for the pain. He was induced to try the movement-cure, and soon got the use of his limbs and hands again. Another case was that of a lady and her servant, who were both attacked in the same way and with about the same degree of chronic rheumatism. The servant takes the movement-cure and goes on with her active work, while the lady gets worse in her soft but dangerous repose. It is well known to us all that men are less subject to these troubles, owing to the fact that they are mostly more active than the women. While insisting on the patient "moving on," a general treatment must also be given, the stomach, kidneys, and skin must be watched with care as to the proper exercise of their functions, and everything that can bring up the organism and give it tone should be used,—meat, beer, iron, cod-liver oil, arsenic, iodine, mineral waters, etc.

For medication the preparations of the iodides are to be preferred, and Dr. Trastour gives the following formulas, which he recommends to be continued for a long time: Iodine (1 gramme) and iodide of potassium (10 grammes), dissolved in distilled water (300 grammes); or, iodide of calcium (10 grammes), combined with lime-water (50 grammes), given in distilled water (250 grammes). Of either of these the dose would be a teaspoonful with noon and evening meal, given in wine or milk.

As to additional local treatment, massage or friction with a stiff whisk broom or broom-brush is recommended, with occasional sulphur baths. To those rheumatics who submit themselves to this sort of treatment early, it is claimed a considerable amelioration will result, and very often a complete cure. In place of crutches, parallel bars must be placed in the room until the patient can walk a little, and then a chair is given to push ahead of him, which afterwards may be given up and two canes substituted. (Professor Rendu, of Paris, gives pure tincture of iodine, in five-drop doses taken in wine, in chronic arthritis.)

Hysterical Symptoms transferred from One Patient to Another by the Use of the Magnet.—M. Babinski, who is "chef de clinique" to Professor Charcot at the Salpêtrière Hospital, has been making a series of very curious experiments that are attracting a good deal of attention here. They were intended to show that certain hysterical manifestations can be transferred by the use of a magnet from one patient to another, even when they are at some distance apart. In this way he was able to transfer different forms of paralysis, such as brachial monoplegia, hemiplegia, coxalgia, and dumbness. One of the experiments was as follows. A young, hysterical woman, who had been dumb for the last two or three years, was one of the patients operated upon, and the other was a hysteric who could be hypnotized. The patients were brought in apart: the dumb girl was first brought in and put in a chair, and a large, close screen was drawn around her so she could not see the other woman, who was now brought in hypnotized (in the magnetic sleep). She was in turn placed on a chair at a little distance from the screen, so that there was no immediate communication between the women. She was then submitted to the action of the magnet, and in a few minutes she was ordered to speak by M. Babinski, but she could not articulate a word, while the other patient (the dumb one) on being touched with the magnet was able to answer clearly all questions put to her. Every precaution was taken so that it would be impossible to say that this effect was produced by suggestion or by any

simulation. The action lasts but a few minutes, and the patients quickly return to their original state. In further experiments, however, M. Babinski reports to the last meeting of the Société de Biologie that a considerable amelioration was noticed in certain cases of spontaneous paralysis, and in one case of hemiplegia following an attack complete disappearance of the paralysis was obtained after four consecutive experiments. So that we may have here a new method of treatment which, when followed up, may lead to important results that we will report in due course.

The Fasting Men.—The arrival of Signor Succi here, who fasted thirty days in Milan, with the aid of a marvellous liquid that he drank first, and the fact that a young Italian named Stefano Merlatti has undertaken to fast fifty days with nothing but filtered water, has caused considerable stir in scientific circles. It is not at all likely that Succi will find any of the serious doctors of Paris willing to act on a committee to watch the effect of his liquor in regard to fasting, but Merlatti has induced several medical men to watch and control his experiment to prove that a long fast can be done without the aid of any mysterious drugs. It came about in this way. Many of the Paris daily papers have doctors who are attached to their staff to write scientific articles for their columns, and a certain Dr. P. Maréchal had written in the *Voltaire* very strongly against Succi and his liquid, and gave it as his opinion that a man could not honestly fast more than ten days. This brought a number of all sorts of people to the doctor's door with offers to prove that they could fast for a number of periods from ten to fifty days. Merlatti wrote to him from London, and said that he had already fasted thirty-six days and would do fifty. Although no answer was given to him, he came over to Paris, and a committee was formed consisting of Drs. Maréchal, P. Collin, A. Combe, E. Monin, and P. Dutrieux Bey, and Dr. Audhoui, physician to the Pity Hospital, was induced to act as consulting physician. The Grand Hotel gave a parlor and bedroom on their first floor, and the fast began by Merlatti eating a good dinner and agreeing not to take anything but water for fifty days. We were invited to call as often as we liked to see the experiment, and had some conversation with Merlatti. He says he was born at Mondovi, near Turin, Italy, on March 21, 1865. He is a slight, boyish, dark Italian, who has been working at drawing in London for a year or so. He is quite intelligent, speaking French and a little English, besides his native tongue. He told us that he first fasted ten days as a boy of twelve: his teacher had beaten him, when he ran away off to the woods and had nothing but water for ten days. Afterwards, in London, he made a bet with his fellow-workmen that he could go forty days without any food, and he says he actually did go thirty-six days, while watched by his friends. The present trial seems to be made with every precaution as to honesty. Two men watch him all day, and one all night, while the doctors call twice a day. His weight before starting was 61 kilos 200 grammes. On the tenth day, when we saw him, his weight was 57 kilos 100 grammes, pulse 72, temperature 37° C., dynamometer 140, spirometer 2.400, and total urea 4.6 grammes. On the twentieth day, when we saw him again, he looked a good deal emaciated, and his pulse was 72, temperature 36.8°, weight 53 kilos 850 grammes, and urea only 2 grammes. He said that his head ached a good deal, but he felt well otherwise, and he did not care for food after the second day. He says he is determined to continue for the fifty days, but Dr. Audhoui says if he loses more than a third of his weight he will tell him to stop.

About the scientific value of this experiment not much can be said; the doctors admit that; but nevertheless it is a curious thing that a man can exist so long without food as even the twenty days now past. No doubt it is very risky in physiological life to live on capital, and, as far as we know, it cannot result in good unless from the rest it affords to the principal organ of digestion in ulcerous complaints or gastritis.

Combination of Antiseptic Substances.—Certain of the antiseptics cannot be applied to all the tissues at a degree of concentration sufficient to produce their antiseptic effects without danger, owing to the fact that they are caustic or otherwise poisonous. For instance, a solution of bichloride of mercury of one to thirty thousand cannot be used upon the pulmonary parenchyma.

M. Lépine has been experimenting to get a solution that would be harmless, and at the same time unite and augment the effects of the different antiseptic substances. He gives the following in solution in distilled water:

One-hundred-thousandth part of corrosive sublimate.
One-thousandth part of salicylic acid.
One-thousandth part of carbolic acid.
One-half-thousandth part of benzoic acid.
One-half-thousandth part of chloride of lime.
One-ten-thousandth part of bromine.
One-two-thousandth part of hydrobromic acid of quinine.
One-two-thousandth part of chloroform.

This composition is not at all irritating, and it has the very strongest kind of antiseptic properties, seeming to act with the full force of each ingredient.

Some Inconveniences of the Milk-Treatment in Stomach-Diseases.—Professor Debove gives

the following history of a patient, which proves that we should use more care in the indiscriminate use of the milk-treatment in stomach complaints. Two years ago the man in question presented all the usual symptoms of alcoholic gastritis: his hands trembled, he had pyrosis and pains running to his back, and later he vomited blood, giving rise to the supposition of ulcer of the stomach. Upon consulting a doctor he was advised to take two quarts of milk a day. He followed this treatment conscientiously, and he was before long in such a state of weakness that he was brought to the hospital, where he was advised to take eight quarts of milk a day: at first he did fairly well, but later he had lost over thirty pounds in weight. When Dr. Debove saw him he was not able to walk nor even to stand up, and he had an enormous dilatation of the stomach, proved by washing it out, as some three quarts of liquid were withdrawn. This washing out was renewed every day, and only a quart and a half of milk was given, with some solid food. After three months' treatment the patient was well enough to be sent to the country for his health.

It results from this that milk must be employed with some limit as to measure to obtain its incontestably good effects.

THOMAS LINN, M.D.

PARIS, November 19, 1886.

NEW YORK.

THE Meeting of the State Medical Association.—The Third Annual Meeting of the New York State Medical Association was held at Lyric Hall, New York, November 16, 17, and 18, Dr. E. M. Moore, President. The number of casual listeners seemed to be smaller than at the first two annual meetings, but the number of members who registered, being about one hundred and fifty, was nearly equal to that of the two preceding meetings. The attendance from New York City and Brooklyn seemed to be diminished, but this perhaps was made so intentionally, as only members or those holding a card of admission could enter the hall. The number of physicians from without the State who had by invitation prepared papers to read before the Association was a noticeable feature, and added not a little to the attractiveness of the meeting. Of these, Drs. Varick, of New Jersey, John B. Hamilton, of Washington, C. T. Parkes, of Chicago, and C. B. Nancrede, of Philadelphia, participated in the discussion on "Shot-Wounds of the Intestines;" Dr. James Tyson, of Philadelphia, took part in the discussion on "Eclampsia." The subjects discussed in the papers were generally practical, and at least interesting, and as a whole were handled in a very creditable manner. The younger physicians who had not had a large experience in writing showed a marked improvement in the preparation of their papers over former years. If any general objection could be made, it probably would be that the writers attempted to treat of their subjects too exhaustively. This view was the more forcibly impressed because of the large number of papers presented: each author prepared his paper apparently without a knowledge of what the others had written, and although assigned a particular part of the subject for consideration, the introductory or general remarks in the several papers, while presented in different words, were essentially the same. This was most apparent in the discussion on "Shot-Wounds of the Intestines," as the authors held nearly the same views, and had previously made them known to the profession through medical societies and journals. It was least observable in the discussion on "Eclampsia," as here there was a marked difference of opinion regarding the cause, the treatment, and the prognosis of the disease. The real views of the participants in the discussion, uninfluenced by the opinion of that or the other eminent authority, would probably be more nearly arrived at in an off-hand discussion, although with a less display of learning.

In the discussion on "Shot-Wounds of the Intestines," participated in by Drs. W. S. Tremaine, J. D. Bryant, E. M. Moore, W. T. Bull, T. R. Varick, C. B. Nancrede, F. S. Dennis, J. B. Hamilton, and C. T. Parkes, there was general unanimity in the view that laparotomy should be performed, the intestinal wounds closed, and the abdominal cavity cleansed. The difficulty of the procedure, however, was admitted. To assist in an exact diagnosis, Dr. Hamilton claimed that it was good surgery to probe the abdominal wound, using not too small a probe and exercising care in order to avoid puncturing the peritoneum or gut.

Regarding pulmonary tuberculosis (discussed by Drs. H. D. Didama, John Cronyn, H. M. Biggs, H. L. Elsner, W. H. Flint, and John Shrady), Dr. Didama claimed that it had not been shown to be hereditary in the sense that the newly-born infant ever had pulmonary tubercles; that in the large majority of cases consumption manifests itself in persons whose parents were not consumptive; precautions should be taken to avoid possible contraction of pulmonary tuberculosis from those suffering with the disease. Dr. Elsner claimed that, in the present state of our knowledge, we were justified in speaking of bacillary tuberculosis and of non-tuberculous consumption.

In opening the discussion on eclampsia, Dr. Lusk presented the different views which had been advanced regarding the causation of puerperal eclampsia, and thought that a sufficient number of cases had been reported in which there was no evidence of renal disease to prove that uræmia could not be claimed as the exclusive exciting factor. Dr. Thomas

had seen only two cases out of a large number in which there was absence of definite signs of kidney-complication, and Dr. Tyson also took the view that in the very large majority of cases the cause of puerperal eclampsia was to be looked for in disease of the kidneys. Dr. Thomas said that in a case with mild symptoms he might temporize with purgatives only in case there was an experienced physician in attendance. His experience differed from that of Dr. Thomas, who had found the only safety to lie in induced labor. According to his observation, the conclusion of gestation causes a cessation of the convulsive symptoms. He had seen two cases in which the convulsive symptoms ceased immediately after the death of the fœtus, although the dead body remained in the womb for some time afterwards. Dr. Colvin, on the contrary, had found the induction of labor seldom called for when the physician resorted to venesection at each occurrence of convulsions, regulating the amount of blood drawn by the effect upon the pulse. He also gave cathartics and employed other general measures. Dr. E. D. Ferguson said he had seen twenty-five or thirty cases of puerperal eclampsia, and none had resulted fatally except those in which violent measures were employed connected with the induction of labor. Dr. E. D. Moore regarded the employment of chloroform, which some of the speakers had recommended, as dangerous, especially as its administration would have to be unduly prolonged if continued to the cessation of the convulsions; whereas ether could be given as long as there were any symptoms of convulsions. He also gave an active cathartic, and the most effective at the time of the convulsions was croton oil. Sulphate of magnesia was more suitable to the case, and should be employed after the convulsions had ceased and during the remaining weeks of pregnancy. Dr. MacGregor, in considering the question, In what proportion do the insane in public asylums owe their insanity to puerperal convulsions? arrived at the conclusion, from correspondence with the medical authorities of over sixty asylums, that a causative influence between puerperal eclampsia and insanity had yet to be shown.

An interesting paper was that read by Dr. Alfred L. Carroll, on "Recovery *versus* Cure." The author showed in a somewhat caustic manner the presumptiveness of physicians in so commonly attributing the recovery of patients to the effect of drugs administered, rather than to the efforts of nature, whose constant tendency was to overcome disease if the patient would only cease to violate the health-laws. That the tendency of the diseased was towards recovery was evident from the fact that they did recover under a great variety of opposing methods of treatment,—at the hands of the quack, the homœopath, the commercial medical advertiser, as well as at the hands of the regular physician. The lesson drawn was, "Be content to do nothing unless you are sure you can do good."

An interesting specimen, consisting of a large mass of hairs matted together, and causing death by its presence in the stomach, was presented by Dr. Finder. Dr. Alvin A. Hubbell reported a case of congenital stenosis of the nose from a thin partition of bone, which was overcome by a hand-drill. The passages again becoming occluded, the openings were again enlarged and kept dilated for some time by the patient wearing a tube of block-tin.

There were about fifty papers read altogether. The Association still holds to the rule adopted at the last annual meeting, of allowing no paper to appear in the volume of Transactions which had previously been published in a medical journal.

Dr. Isaac E. Taylor, of New York, was elected President.

Medical Society of the County of New York.—At the adjourned annual meeting held November 22, 1886, Dr. John C. Peters, of the Committee on Hygiene, read an additional report, in which the committee recommended that the baling of stable-manure be enforced in every practicable and reasonable way. The advantage of this method of disposing of the manure was that it could be baled inside of the stables, doing away with the filling and emptying of sidewalk manure-pits.

On recommendation of the Treasurer, a resolution was passed providing for the payment out of the treasury of the dues of members who were in arrears and whose present circumstances would make it embarrassing for them to pay such dues; and providing also for the expulsion of members who were able to pay their dues but refused to do so.

Dr. Daniel Lewis, President of the Society, read a brief address, in which he spoke of the harmonious relations existing between the Academy of Medicine and the County Society, of the desirability of a complete membership from among all honorable physicians in the city. He then introduced the President-elect, Dr. Laurence Johnson, who called the stated meeting to order and proceeded to read his address, in which he dealt with the subject of the relations of the Society to the public at large, to the Board of Health, to the general profession, and to itself. He spoke of medical charities, and thought one way to avoid their abuse was for the physician to base his charges to poor patients upon their ability to pay, and not necessarily according to the value of his services, which perhaps could be paid only by the well-to-do or the wealthy. The poor of New York constitute nine-tenths of the population. The paupers could be left for the care of charity institutions proper. Regarding specialism, he said there are

specialists evolved from general medicine, and these and the general profession were always in close sympathy with one another; but there are also specialists who were not evolved from general medicine, but as it were from the raw material, and these had no sympathy with the family physician, and the general profession could have little with them; the subject of general medicine had no interest for the latter class of specialists.

Dr. James O'Reilly, against whom charges were made, was expelled from the Society.

It was resolved to continue the publication for another year of the "Medical Directory of the City of New York," to be edited by the Comitia Minora. R. C. S.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CLINICAL meeting was held November 17, 1886, Dr. William Osler in the chair.

Dr. J. C. Wilson read the report of a case of "Peritonitis in Enteric Fever, terminating in Recovery, with Remarks" (see page 175).

DISCUSSION.

Dr. Frank Woodbury: The recommendation of the lecturer with regard to operative interference at once raises the interesting and important question of diagnosis. Two classes of cases are at once recognized,—peritonitis with perforation, and peritonitis without perforation. The suggestion with reference to operation generally would apply only to the former. Cases also in which there is bursting of an infarct of the spleen or in which septic material is thrown into the peritoneal cavity from any other source would come under the same head. I think in such a case, if other circumstances do not specially forbid the operation, the suggestion of Dr. Wilson is one that might be acted upon. Where perforation occurs in typhoid fever there is not only foreign matter in the peritoneal cavity, but intensely poisonous foreign matter, and we might in these cases open the abdomen and try to render the field aseptic, just as has been done successfully in suppurative peritonitis from other causes. In typhoid fever we not only have the special bacteria of this disease, but, owing to the absence of the gastric juice for several weeks and the almost entire abolition of the function of digestion, there is a collection of sordes along the gastro-intestinal tract which serves as a culture-medium for all kinds of micro-organisms. When the gut is opened and this fluid is poured into the peritoneal cavity, it is clearly our duty, if considered from a surgical stand-point alone, to remove it if possible. At the same time, I should not say that all cases of peritonitis due to perforation of the bowel should be operated upon. We know that cases of peritonitis with perforation occurring in the course of typhoid fever sometimes recover with the aid of appropriate treatment. Opium, which was so successful in the case reported, has also been successful in other cases. We should first eliminate this favorable element from the prognosis. If the case were one that could not recover otherwise, we might formulate the law that it should be operated upon: even if the chance is a desperate one, it would be the patient's only chance; but I make the point that some cases of perforation do recover without resort to surgical measures, although I admit that the result is usually a fatal one.

In the cases of peritonitis without perforation, the extension of inflammation from the mucous to the serous coat by contiguity has always seemed to me an exceedingly hypothetical explanation. In hospital practice I have seen at least two cases coming under my care late in the disease in which there was pyæmia. There were collections of pus around the joints and under the skin. Now, peritonitis is not a rare occurrence in pyæmia; and it seems to me that this should be considered as one of the possible causes of peritonitis where it occurs without perforation in typhoid fever. In rare instances, then, the cause of the infection is through the blood, but it may be more direct. Who can say, at the post-mortem examination, that there has not been a minute perforation in the very thin wall of the intestinal ulcer which has been sealed by lymph before death? A pin-hole perforation sufficient to allow the extension of inflammation from the mucous to the serous coat may have existed and afterwards closed, so that it may become an impossibility to discover it.

I wish to call particular attention to a condition which may simulate peritonitis in just such cases as have been described to-night, and which is interesting from a diagnostic point of view. I have met with it in a number of patients who had been treated with the greatest care as regards diet, and every effort made to avoid irritation of the bowel. The case goes on to defervescence, and within a week after the temperature has reached the normal the patient partakes of a meal of bread and soft-boiled egg, usually at breakfast-time. The result is that on the same evening there is a return of the fever, with abdominal tenderness, tympany, and diarrhœa, and sometimes a few spots reappear upon the surface of the abdomen. In the condition of the intestinal tract present after typhoid fever the albumen of egg seems to act as a poison, at least in some patients. I merely mention this to show the possibility of confounding the two conditions. I now avoid this recrudescence of the fever by simply omitting the albumen of the egg from the dietary and giving the yelk alone, with milk or wine, two or three

times a day. This is generally well borne and causes no irritation.

I was much interested in the case reported, but I was unable to gather from Dr. Wilson's remarks whether or not there were evidences of effusion. This would of course be an important element in the diagnosis of peritonitis.

Dr. William Osler: I think that the cases of peritonitis following typhoid fever can be grouped into three sets. The first group is that in which perforation occurs from the depth of the slough. This constitutes the largest group of cases, and the fatal event is most apt to take place in the second or third week. I have seen it as early as the tenth day, if not earlier. In these cases the condition of the patient is, as a rule, such that the operation of laparotomy would scarcely be indicated: the patients are so profoundly overwhelmed by the severity of the attack that they are in no condition to stand an operation; the ileum, moreover, on which the operation would be performed, is in a most unfavorable condition for surgical interference, the wall of the gut being infiltrated and swollen.

In a second group of cases the operation might be successful. In these instances the sloughs have already separated, but the ulcers remain, and from some indiscretion, usually in diet, a slight tear takes place at the bottom of the ulcer, with the development of peritonitis, which is usually fatal. This may occur late in the disease, long after the fever has subsided and the patient is supposed to be convalescent. One such instance I have reported, in which the perforation occurred between two and three weeks after the temperature became normal. It resulted from the patient eating two or three chops which were injudiciously given to him. The patient died within thirty-six hours after the occurrence of the rupture. In this case there was found an unhealed ulcer with a narrow rent at the bottom.

The third group is a very limited one, in which the peritonitis has resulted from the extension of inflammation from a slough or ulcer. While peritonitis from this cause is not very frequent and is not very extensive, I can state positively that it does occur.

I think that in the cases in which perforation takes place as the result of indiscretion in diet during convalescence, laparotomy would be indicated. In the first group of cases the operation would probably do no good. An interesting question arises in this connection, and that is how soon in typhoid fever we should return to a more solid diet. I make it a rule not to give solid food for at least ten days from complete evening defervescence.

Dr. Wilson has spoken as though a large quantity of fecal matter escaped into the peritoneal cavity in the perforation occurring in typhoid fever. It is exceptional in my experience to find in these cases a large amount of fecal extravasation. Adhesion of the coils of intestines rapidly takes place and prevents this.

Dr. Frank Woodbury: What is the criterion of inflammation in a serous membrane?

Dr. William Osler: Practically, as applied to the intestine, neither redness nor swelling, but lymph: perhaps not lymph that can be distinctly peeled off, but sufficient to dull the normal glossy appearance of the membrane. That is, I think, the criterion of inflammation in the peritoneum, the pleura, and the pericardium.

Dr. Woodbury: That I understand to be the usual histological criterion of inflammation; the pathological one is that inflammation is nature's reaction against an irritant. In the case in question this irritant is nothing more nor less than a form of bacteria. I would ask, in the absence of septicæmia, how the fluids containing the bacteria can get from the interior of the gut to the serous membrane outside without the existence of a perforation, however minute? It seems to me that there must be a direct means of egress in these cases through the intestinal wall from the mucous to the serous surface.

Dr. J. Howard Reeves: I would like to report a case of mild typhoid fever in which imprudence in diet was followed by a series of rigors, hemorrhage from the bowels, and peritonitis; the peritonitis continued nine days, and was followed by recovery; the typhoid convalescence was very slow.

Dr. J. C. Wilson: I may say to Dr. Woodbury that in the case reported there was no error in diagnosis. It was carefully examined from every point of view both by myself and by Dr. W. W. Keen.

I recognize the propriety of the remarks of Dr. Osler. When I spoke of extravasation of the intestinal contents I did not mean to imply that a large quantity was thrown out. In enteric fever the nature of the intestinal contents is such that a small quantity may set up a very serious inflammation. On two occasions, however, I have found scybalous masses in the peritoneal cavity, and in one case recovered a fragment of sweet potato.

I recognize the force of his division of the cases, from the pathological stand-point, into three groups. The second group of cases is certainly the most available for operation to save life, but I do not believe that even the first group should be wholly excluded from consideration. Many cases of traumatic peritonitis have been saved by operation during the past few years which no one, five or ten years ago, would have thought of subjecting to operation. The operation should be done in cases of impending death from perforation with the slim hope that it will succeed. If the operation be performed—as I confidently expect—in enteric fever, it will be at first in the

second group suggested by Dr. Osler; if it succeeds there, it will be after a time considered right to operate even in the first group.

Dr. William Osler read a paper on "Duodenal Ulcer: Clinical and Anatomical Considerations based on Nine Cases."

DISCUSSION.

Dr. John E. Whiteside: The patient whom Dr. Osler saw with me had suffered with dyspepsia for a number of years previous to his last illness. The abdominal pulsation which has been referred to was at times extremely distinct. I agreed with Dr. Osler that this was probably due to aneurism. The first vomiting took place four days after the patient was seen by Dr. Osler. A few days later the patient was taken with a violent attack of pain, and died within fifteen minutes. The post-mortem examination at once explained the trouble, for the whole abdominal cavity was filled with blood.

Dr. William E. Hughes: I wish to put on record a case in which the diagnosis of duodenal ulcer was, I think, confirmed by the subsequent history of the case. The patient was a farmer, 26 years of age, who had complained for about two years of dyspeptic attacks. Under an exclusive milk diet the dyspepsia was much lessened, but did not entirely disappear. The main symptom was extreme pain, which appeared two or three hours after eating. It was located to the right of the epigastrium, and was accompanied with slight tenderness. On several occasions after these attacks of pain the patient passed large quantities of pretty fresh blood by the bowel; the general condition was fairly good. He then went to the country. Some time later his physician wrote to me after one of the attacks of pain the patient passed into a condition of collapse, from which he reacted, and two or three days later a fluctuating mass developed in the epigastrium to the right of the median line. I have been unable to obtain any further information in regard to the case.

Dr. Frank Woodbury: I wish to report a case of ulcer in the upper part of the small intestine. A young woman aged 22, a schoolteacher, while at her occupation, and apparently in health, was taken with severe pain in the abdomen, and was brought into the German Hospital. Peritonitis developed on the following day, and she died that night. At the autopsy a small, round, perforating ulcer was found in the upper part of the jejunum; a large lumbricoid worm was also found in the vicinity. The question was discussed whether there was any connection or not between the presence of the worm and the thinning of the gut.

Dr. William Osler: The pain in duodenal ulcer is very irregular and variable; the attacks may come on after meals or independent of the taking of food; there are instances in which pain has been entirely absent.

A remarkable feature is the length of time that these cases last. There are cases on record in which the duration has been ten or fifteen years.

The pulsation observed in Dr. Whiteside's case was probably due to the anæmic condition and to the fact that the thickened head of the pancreas and the thickened ulcer were immediately over the aorta, which in systole pushed up the left lobe of the liver and produced the wave of pulsation which was so visible.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED MEETING, OCTOBER 7, 1886.

The President, B. F. BAER, M.D., in the chair.

(Continued from page 165.)

DR. BAER also presented the specimen and related the history of

A MONOCYST OF THE OVARY.

Mrs. J., aged 29, married four years, sterile; puberty at fourteen years of age, and menses always normal. Seven years ago she first discovered that the lower portion of her abdomen was increasing in size. This continued very slowly during the next three years, and at the time of her marriage it was large enough to be perceptible to her friends. It ceased growing until six months previous to the date at which she first consulted me, April 14, 1886, when she seemed to be in excellent health; no loss of flesh, no pain; complexion ruddy, and appetite good. Menstrual flow increased, and accompanied with uterine tenesmus during the last two months; and she had begun to complain of pressure and over-distention. When the patient was in the dorsal position the abdomen did not flatten out, and it was symmetrical and smooth. Dulness on percussion over the anterior and lateral surfaces of the projecting portions of the abdomen, with resonance in the line of the colon. There was marked fluctuation in the dull region. Vaginal examination showed the uterus anteverted, of normal size, not freely movable, yet not closely adherent to the tumor.

Diagnosis, probably cyst of the broad ligament, from the long existence of the tumor, its slow growth, symmetrical development, together with the fact that it had not influenced the patient's health during its growth until it had attained such size as to interfere with respiration. Its removal was advised, and the operation was performed at my private hospital April 27. An incision three inches in length was made. The tumor was rather darker in appearance than is usual in cysts of

the broad ligament. It was now tapped and a dark grumous fluid drained away. The tumor collapsed and was easily drawn through the incision, when its pedicle was found to consist of the entire broad ligament and to be very short, holding the base of the tumor deep in the pelvis. I was compelled to enucleate the cyst, leaving a broad open pedicle or surface which I ligated *en masse*.

An accident now occurred from which the patient almost lost her life from hemorrhage,—viz., slipping of the pedicle ligature. The mistake was in endeavoring to make a pedicle of the broad ligament, which had been laid widely open by the enucleation of the tumor, and which was not a proper pedicle. The mass was too great to be held by ligature, and was treated by bringing the edges together by interrupted sutures, of which ten were required. The hemorrhage was checked by grasping the vessels in clamp-forceps until the sutures were placed. There were no after-symptoms. The patient is now entirely well.

I call attention to the monocystic character of this tumor, its location in the broad ligament, and to the character of the contained fluid,—dark-colored and thick, not clear and limpid as is usual in cyst of the broad ligament proper.

The report of Dr. Formad is: "The cyst is a monolocular one, developed from the ovary undoubtedly. Its lining is characteristic of ovarian cysts, epithelial, and whatever scrapings from the wall could be obtained showed the ovarian cells of Drysdale. The fluid was dark, grumous, and turbid, which excludes cysts of the broad ligament or parovarium, as the latter kind of cysts have always a limpid clear liquid."

Dr. B. F. Baer also presented the specimen and read the history of

A CASE OF BURSTING CYST OF THE OVARY.

Mrs. E. G. was sent to me by her physician, Dr. James Simpson; she was 47 years of age, and had been married twenty-seven years, but had never been pregnant; puberty at fourteen years; menstruation always painful. She stated that twelve years ago she had felt a "lump" in the left iliac region; this was painful, especially during the menstrual period. In the fall of 1885 the lower part of her abdomen began to enlarge, and within a few months it had so increased in size as to render locomotion and respiration difficult. On January 1, 1886, while riding in a street-car, she was jolted in crossing a railroad-track. She was at once seized with great pain in the abdomen, accompanied with pallor and faintness. She was taken home and placed in bed; a short time afterwards she began to vomit a fetid fluid which came up in large quantity and at regular intervals, and at the same time she passed fluid of the same character from the bowels; the next day she had, in addition, attacks of profuse perspiration; she also had a slight metrorrhagia, the first evidence of menstrual flow since January, 1884. The abdomen rapidly diminished in size, and within a week had regained its normal dimensions. It was three weeks before her strength had returned sufficiently to permit her to go about. She soon noticed that her abdomen was filling up again, and within a month it had become as large as it had been on January 1. During the first week in March she was again seized with pain of the same character, and followed as before by vomiting, purging, diuresis and diaphoresis, and reduction of the abdominal distention. All of the symptoms were more marked in the second attack. Six weeks afterwards she was as large as ever, and she then came into my care.

She presented an appearance of great pallor and commencing emaciation; the "facies ovariani" becoming plainly perceptible. She was very nervous and excited for fear of a repetition of the phenomena that had occurred before.

On examination in the dorsal position the abdomen was rather projecting, not flat, and was larger on the right than on the left side; it was smooth throughout, and gave a dull sound on percussion over the whole anterior surface, resonance existing in the line of the colon. There was marked fluctuation throughout the dull portion. Vaginal touch showed the uterus to be situated high as if it were drawn upward; it was not freely movable, and the external os was too small to admit the sound.

Diagnosis, ovarian cystic disease. Immediate operation advised.

On July 22 the operation was performed at my private hospital. Incision three inches, in median line; wall of the tumor thin and dark-colored. The trocar was passed and the contained fluid, dark in color, drained away. The cyst collapsed and was easily drawn through the incision. The pedicle was short and broad, consisting of the broad ligament, and requiring enucleation of the tumor before its ligation could be accomplished. It was now found that another tumor existed on the left side. This had a peculiar shape, being elongated, and deeply seated in the pelvis as though it were entirely sub-peritoneal. The peritoneum extended out from the uterus, spreading over the tumor, and approaching the abdominal wall as is sometimes seen in a fibroid tumor of the uterus which has pushed that membrane upward in its growth; the cyst extended along the line of the colon, and at first I was not sure that it was not that organ greatly distended by gas. I soon determined that it contained fluid, and that its general appearance, color, etc., were similar to those of that just removed. It was emptied by means of the trocar of a fluid similar to that of the first tumor, and the tumor collapsed. I hesitated as to the proper course now, because

of the large and broad base of this cyst and its close adhesion to the descending colon. I first thought of stitching it to the abdominal incision and inserting a drainage-tube into it, and was soon afterwards sorry that I did not follow out my first idea. I began an attempt at enucleation, and this was attended by so much hemorrhage from the large surface which it was necessary to dissect that I was compelled to desist. I had separated at least six inches of the descending colon from the cyst when I found that the latter dipped down so deeply into the pelvic excavation that I concluded it would be hazardous to finish the enucleation. I was in a quandary, for I had only two-thirds of the lining membrane of the cyst in my control, and I finally did what I was never compelled to do before,—and what I may be criticised for doing in this case,—I drew up as much of the cyst as was possible, threw a ligature around the mass, tied it as a bag, and cut away the external portion, thus leaving a large quantity of the lining membrane still within the pelvis. The oozing of blood from the large open surface was checked by ligatures and compression-forceps until the bleeding had ceased; the toilette of the peritoneum was then made, a drainage-tube inserted, and the incision closed. During the next few hours there was a free discharge of bloody serum through the tube, but by the next morning it had ceased. On the third day the tube was removed. The patient made an excellent recovery, and went home on the twenty-third day.

The points of interest in the case are:

1. The bursting character of both the cysts.
2. Their monocystic character and probable ovarian origin.
3. The deep attachment of the one on the left side, and its partial removal only.

"Bursting Cysts of the Abdominal Cavity" is the title of a very instructive paper which was read before the Gynæcological Society in 1881 by Dr. William Goodell, and in the paper itself and the discussion which followed it was shown that this character of tumor is not so rare as the experience of a single individual might indicate. In addition to the cases which Dr. Goodell himself reported, three in number, there were no less than ten of the members present who had met with cases of a similar character, some of the gentlemen as many as six or seven. Only two or three of the cases reported died as the result of the discharge of the fluid into the abdominal cavity. This appeared to prove that the fluid of an ovarian cyst was not so irritating to the peritoneum as had been supposed. Dr. Goodell took the position that these cysts were of the broad ligament or parovarium, and not true ovarian cysts, and, as a consequence, the fluid was bland and unirritating, being readily absorbed and discharged through the emunctories. This view is probably correct for the majority of cases, but there are others where the evidence furnished by operation has proved the origin of the bursting cyst to have been in the ovary. The monocystic character of the tumors in this case, and their location beneath the peritoneum, within the folds of the broad ligament, would seem to indicate that they originated in the parovarium and not in the ovary; but the character of the fluid and its rapid secretion are in favor of an ovarian origin.

An interesting feature in this case is the fact that the fluid was discharged by vomiting and purging, as well as through the bladder and skin, showing that it must have been emptied into the abdominal cavity as well as into the intestinal tract. From the close attachment of the tumor on the left side to the colon, it is probable that this cyst discharged itself into that organ and was thus thrown off by vomiting and purging; while the fact that diuresis and diaphoresis took place at the same time in such quantity, and that the abdominal distention entirely disappeared, would lead to the conclusion that both cysts must have burst simultaneously, the one discharging into the bowel, the other into the peritoneal cavity. This is interesting if true, and probably unique; at least I have not been able to find a record of a similar case. I examined this patient recently, and found only a slight induration on the left side; she has been quite well.

Dr. HARRIS mentioned a case of bursting cyst that had been sent to Dr. Atlee for operation after the cyst had burst once and refilled. The day had been fixed for operation, but, menstruation coming on, a postponement was made, and the cyst again burst, and the woman died in collapse. Ovarian tumor had been diagnosticated.

Dr. PARISH reported a case of rupture of an ovarian cyst which occurred in the "old women's ward" at the Philadelphia Hospital. The rupture was spontaneous while the woman was in bed; she died in a few minutes from shock. In another instance, in which rupture had not been suspected, one cyst, the contents of which were colloid, had burst, another ovarian cyst was found and removed There was no evidence of acute inflammatory action.

Dr. BAER exhibited a

FIBROID POLYPUS OF THE UTERUS.

The patient had suffered from metrorrhagia for two or three years. Labor-like pains were followed by spontaneous expulsion of the tumor, which was supposed by three physicians to be an inverted uterus: it was replaced in the vagina and tamponed. Dr. Baer found the uterus in normal position, and removed the tumor by means of the spoon-saw.

W. H. H. GITHENS,
Secretary.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held November 10, 1886, the President, JOHN A. WYETH, M.D., in the chair.

FIBROID TUMOR OF THE OVARY.

Dr. H. MARION SIMS presented a double fibroid tumor of the ovary, with the following history. The patient, aged 48 years, had borne two children, the youngest sixteen years ago. She had always enjoyed excellent health until about five years ago, when she began to suffer from bearing-down pains, pain in the back, and inability to walk or stand with comfort. About two years ago she noticed quite a large lump in the right side of the abdomen. This grew, and with its growth the pain increased in violence until a few months ago she was unable to leave the bed. Dr. Sims made the usual abdominal incision, and found a double fibroid tumor of the right ovary, with few adhesions, which he easily removed. The patient recovered without an unfavorable symptom, and had remained well. The case was interesting because of the rarity of purely fibroid tumors of the ovary.

DOUBLE ANEURISM OF THE HEART.

Dr. THATCHER presented a heart which he saw after the autopsy had been made by another physician. The history of the case was imperfect, but the woman was about 50 years of age, had had eight abortions, had an attack of rheumatism about two years ago, since when she claimed to have been unable to work, although about three days before death she was able, her friends stated, to go on a spree, to which they attributed her death. She seemed to have died of heart-failure. The heart alone came into the possession of Dr. Thatcher. It presented two aneurismal sacs near the apex, the one of the size of two fists, the other of the size of a single fist. Both had a communication with the left ventricle by an opening about the size of a match. Their walls were apparently composed of the two layers of the pericardium, which probably had become adherent to the heart by pericarditis before the ventricular openings had formed. The blood passing from the ventricle through these openings distended the sac, and formed the aneurisms. The walls of the heart were very thick, except immediately around the openings, where little else than the thin fibrous structure remained.

CONGENITAL CYSTIC DEGENERATION OF ONE KIDNEY.

Dr. L. EMMET HOLT presented the right kidney and what remained of the left, removed from the body of an infant aged 10 months. The child had dysentery, and during its illness developed albuminuria. There were no casts, and the amount of urine was normal. The autopsy showed enlargement of the right kidney. It weighed two ounces, and was the seat of acute parenchymatous degeneration, which was accounted for by the high temperature during the last week of life. The left kidney was replaced by a body about the size of a pigeon's egg, composed of one larger cyst and a number of smaller ones, held together by some loose connective tissue, and apparently containing no trace of renal tissue; the ureter was pervious to within an inch of the kidney, but was smaller than the right; the left renal artery was about one-sixth the size of the right; the bladder and genital organs were normally developed.

Dr. ROGERS also presented the kidneys of an infant illustrating the same morbid condition as the specimens presented by Dr. Holt. The history of the child was unknown. The right kidney was found normal, while the left was replaced by several small cysts.

REVIEWS AND BOOK NOTICES.

A MANUAL OF MICROSCOPICAL TECHNOLOGY, FOR USE IN THE INVESTIGATIONS OF MEDICINE AND PATHOLOGICAL ANATOMY. By DR. CARL FRIEDLAENDER. Translated, with permission, from the Second Enlarged and Corrected Edition by STEPHEN YATES HOWELL, M.A., M.D., Buffalo, New York. New York and London, G. P. Putnam's Sons, 1885. Pp. 249.

The remarkable accessions which have recently been made, to the knowledge of the etiology of infectious diseases particularly, have given to medical microscopy increased prominence. This manual treats of the technics of the microscope, the preparation of specimens, and examination of various fluids and solids.

The translator has enhanced the value of this very practical work by adding numerous notes, and by introducing an illustrated article embodying the recent discovery of the comma-bacillus of Asiatic cholera, and treating of its morphology, cultivation, staining, and examination for diagnostic purposes. The book is well printed.

NEW REMEDIES AND CLINICAL NOTES.

EMBALMING DEAD BODIES.—Dr. H. R. Tilton, Surgeon United States Army, writes from San Francisco that he has read the request of Dr. Kennedy for information as to the best, simplest, and most ready method of preserving dead bodies. He has tried the Wickersheimer formula, and says that it is an impracticable method, at least for the general

practitioner. "There is too small an amount of antiseptic material in the Wickersheimer formula to hold out any promise of success. It is impracticable for the average country practitioner to complete the process by immersing the body, after injection, in a solution, and then enclose it in an air-tight case. Fortunately, this is entirely unnecessary. The following formula will preserve the body if the injection is properly done: Take of the solution of chloride of zinc (U. S. Ph.), one gallon; solution of chloride of sodium, six ounces to the pint of water, six pints; solution of bichloride of mercury, one ounce to the pint of water, four pints; alcohol, four pints; carbolic acid (pure), one-half pint; carbolic acid dissolved in glycerin, one and a half pints. Mix all the ingredients, and a clear solution of three gallons results, which is the proper amount for a body weighing one hundred and fifty pounds. The solution may be injected into the aorta, but it is much less trouble to inject into the brachial or femoral artery, or the femoral vein may be selected. If an artery is used, the injection should be towards the capillaries, and if a vein, towards the heart. To satisfactorily inject a subject a good anatomical syringe is desirable, but a gravity-syringe can be improvised with rubber-tubing, a stopcock, and a terminal glass tube with the tip drawn to a fine point. I would suggest to Dr. Kennedy that he experiment on a few animals, and then he can devise a formula to suit himself. I have found that a fluidrachm of the solution recommended is sufficient for each ounce of weight of the animal to be preserved. For preserving human bodies, two and a half fluidounces for each pound is a safe estimate."—*Medical Record.*

Chloroform as a Hæmostatic.—Dr. Betz (*Memorabilien*, 1885, No. 5, *ibid.*) relates two cases of uterine hemorrhage in which he found chloroform of great utility in its arrest. In the first case fearful hemorrhage followed a protracted labor which had to be terminated by the forceps. There was atony of the uterus, and hot water injected into the uterus failed to produce contractions. A sponge, saturated with chloroform, was passed into the uterus, and some chloroform was poured on the abdomen. On the introduction of the sponge, a severe burning pain was felt along the genital passage, strong contractions of the uterus took place, and the bleeding ceased. The second case was one of hemorrhage following an abortion at four months, which continued in spite of the ordinary treatment, and the patient became cold and pulseless. Chloroform was applied locally to the inside of the uterus through the means of a sponge, in the same way as in the first case. The same burning pain was experienced, contractions of the uterus took place, and an arrest of the hemorrhage ensued. The action of chloroform, Dr. Betz observes, differs from that of the ordinary astringents, not inducing coagulation of the blood as they do, but causing narrowing and closure of the blood-vessels in consequence of muscular contraction. The use of chloroform in this way may supersede the hypodermic injection of ether.—*New York Medical Journal.*

MISCELLANY.

Harvard's Jubilee Honors to Physicians.—The two-hundred-and-fiftieth anniversary of the founding of Harvard University was observed with impressive ceremonies last month, the exercises continuing for four days. Honorary degrees were conferred upon a number of distinguished persons, among whom were Joseph Leidy, M.D., Professor of Anatomy in the University of Pennsylvania, S. Weir Mitchell, M.D., of Philadelphia, and J. S. Billings, M.D., of Washington, D.C.

Pennsylvania School of Anatomy.—Dr. George McClellan will give, by request, a course of popular lectures on anatomy on Friday afternoons at 4.30 o'clock. The course is especially designed for instruction in anatomy with reference to art, and it will be illustrated by diagrams, preparations, models, and extempore free-hand drawings.

The Philadelphia School of Anatomy, located at Tenth and Arch Streets, is conducted by Henry C. Boenning, M.D., who also gives courses on operative surgery to students and graduates.

Colden's Beef-Tonic is used with advantage by some physicians in this city in the nervous disorders accompanying malnutrition.

NOTES AND QUERIES.

OBITUARY.

John P. Gray, M.D., LL.D., Superintendent of the New York State Lunatic Asylum at Utica, New York, died at the Asylum on Monday, November 29, 1886, of Bright's disease. Dr. Gray was born in Centre County, Pennsylvania, August 6, 1825. He was educated in the common schools at Bellefonte and at Dickinson College, receiving the degree of A.M. in 1846. His medical degree was received at the University of Pennsylvania in 1848. After serving for a time at Blockley, he went to Utica in 1851 as an assistant physician. In 1853 he was appointed Acting Superintendent, and in 1854 succeeded Dr. Benedict as Superintendent.

As Superintendent of the Asylum, Dr. Gray made himself felt in a way that had a more than local influence. He insisted upon a high standard of general and professional care, and carried his views into every department of asylum administration.

He early established the rule of receiving for assistant medical officers young men of thorough medical training, making general hospital service a prerequisite to appointment. As a result of this high standard and the training received under Dr. Gray, no less than six State asylums have called their superintendents from Utica since his appointment as its chief medical officer.

He took an active interest in hospital architecture, and was the author of the plans for the asylums at Kalamazoo, Michigan, and Buffalo, New York.

As the editor of the *American Journal of Insanity*, and

in addresses before medical societies and other scientific bodies, Dr. Gray contributed largely to the literature of Insanity and Medical Jurisprudence. He was an earnest advocate of the physical basis of insanity, and early omitted from his reports any enumeration of the so-called moral causes.

He took a strong interest in pathological investigations in insanity, and nearly thirty years ago contemplated and suggested the institution of systematic pathological study in the Asylum. It was not, however, until several years later that he was able to put his views into practical operation, when he was the first superintendent to appoint a medical officer in an insane asylum for special pathological work.

The high standard of care of the insane attained by the State of New York is largely due to the influence of Dr. Gray, and the example of Utica has been widely felt, and for good. He was a man of positive ideas, and seldom permitted opposition to intimidate or influence him. In any body of men he made himself felt, and, while in many matters of a conservative tendency, his influence was always in the direction of advance.

As a medical witness in cases of public interest he was widely known. His most exhaustive services in the Guiteau trial are probably the best remembered. During the war, he several times gave the government the benefit of his advice, and his services were employed in the trial of the Lincoln assassins.

In 1874 he was appointed Professor of Psychological Medicine in Bellevue Hospital Medical College, and in 1876 received a similar appointment from the Albany Medical College. Both of these positions he filled with ability. He was a member of the American Medical Association, at one time President of the New York State Medical Society, and recently President of the New York State Medical Association. In 1876 he was chairman of the Psychological Section of the International Medical Congress, and he held the same appointment for the Congress of 1887. He was a member of the Association of Superintendents of Asylums for the Insane, and once its President. The British, French, and Italian Medico-Psychological Associations elected him to honorary membership.

In 1882, Dr. Gray was shot by an insane man resident in the city of Utica. The ball from a large navy revolver entered over the left malar prominence and came out at the centre of the right cheek. From the shock of this, although the wound was not serious, he never fully recovered, and the impediment to free respiration produced by the cicatrization in the course of the bullet, which traversed the floor of each nostril, was a continual source of annoyance.

In the winter of 1885–86 his health became seriously impaired, and the managers of the Asylum gave him leave of absence. He spent some weeks in the South, and returned much improved. In July he sailed for Europe, returning early in October. He felt that the trip had been of benefit, but shortly after his return he was exposed to cold, had a chill, some bronchitis, considerable dyspnœa, and disturbance of circulation. His kidneys had been diseased for some time, but a more active process was lighted up, which terminated in death from uræmic coma.

In his death the profession of medicine has lost an active and earnest practitioner, one who in his special department has added honor and reputation to American medicine, and whose work as an alienist will long continue to influence for good the public care of the insane. E. N. B.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM NOVEMBER 21, 1886, *TO DECEMBER* 4, 1886.

Lieutenant Colonel B. J. D. Irwin, Assistant-Medical Purveyor.—Relieved from temporary duty in New York City, and of the charge of the medical purveying dépôt in that city, and ordered to San Francisco, California, to take charge of the medical purveying dépôt in that city. S. O. 270, A. G. O., November 19, 1886.

Major F. L. Town, Surgeon.—Ordered from Fort Clark, Texas, to Post of San Antonio, Texas, to relieve Surgeon J. P. Wright. S. O. 159, Department of Texas, November 15, 1886.

Major Joseph R. Gibson, Surgeon.—Ordered for duty as post-surgeon, Fort Lyon, Colorado. S. O. 134, Department of Missouri, November 20, 1886.

Major Daniel G. Caldwell, Surgeon.—Granted twenty days' extension of his leave of absence. S. O. 278, A. G. O., December 1, 1886.

Captain P. R. Brown, Assistant-Surgeon.—Leave of absence for seven days, granted by post orders, is extended twenty-three days. S. O. 124, Department of Arizona, November 24, 1886.

Captain E. B. Moseley, Assistant-Surgeon.—Relieved from duty as attending surgeon in San Francisco, California. S. O. 99, Division of the Pacific, November 19, 1886.

Captain Edw. B. Moseley, Assistant-Surgeon.—Directed to take charge of the medical purveying dépôt, San Francisco, California, until the arrival of a proper bonded officer. S. O. 99, Division of the Pacific, November 19, 1886.

Captain Louis S. Tesson, Assistant-Surgeon.—Granted leave of absence for four months, to date from November 13, 1886. S. O. 278, A. G. O., December 1, 1886.

Captain J. L. Powell, Assistant-Surgeon.—Ordered for duty as post-surgeon, Fort Supply, Indian Territory. S. O. 134, Department of Missouri, November 20, 1886.

First-Lieutenant Peter R. Egan, Assistant-Surgeon.—Assigned to duty at Fort Clark, Texas. S. O. 162, Department of Texas, November 22, 1886.

First-Lieutenant William J. Wakeman, Assistant-Surgeon.—Leave of absence extended three months. S. O. 274, A. G. O., November 26, 1886.

First-Lieutenant W. D. McCaw, Assistant-Surgeon.—Granted leave of absence for two months, to take effect when his services can be spared. S. O. 274, A. G. O., November 26, 1886.

First-Lieutenant Freeman V. Walker, Assistant-Surgeon.—Assigned to duty at Fort McIntosh, Texas. S. O. 159, Department of Texas, November 15, 1886.

First-Lieutenant Paul Clendenin, Assistant-Surgeon (recently appointed).—Ordered to report to commanding general, Department of Texas, for assignment to duty. S. O. 271, A. G. O., November 20, 1886.

First-Lieutenant Paul Clendenin, Assistant-Surgeon.—Assigned to duty at Fort Davis, Texas. S. O. 166, Department of Texas, November 29, 1886.

First-Lieutenant C. L. G. Anderson, Assistant-Surgeon (recently appointed).—Ordered for assignment in Department of Arizona. S. O. 277, A. G. O., November 30, 1886.

First-Lieutenant Robert R. Ball, Assistant-Surgeon (recently appointed).—Ordered for duty in Department of the Missouri. S. O. 278, A. G. O., December 1, 1886.

Captain Henry Johnson, Medical Storekeeper, will, in addition to his present duties, assume charge of the medical purveying dépôt in New York City, as Acting Assistant Medical Purveyor. S. O. 270, A. G. O., November 19, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FOR THE TWO WEEKS ENDED DECEMBER 4, 1886.

Surgeon Homer L. Law, U.S.N.—Ordered before the Retiring Board, December 2, 1886.

Passed Assistant-Surgeon George C. Lippincott, U.S.N.—Ordered before the Retiring Board, December 6, 1886.

Surgeon William G. Farwell, U.S.N.—Detached from the "Kearsarge," proceed home, and wait orders.

Passed Assistant-Surgeon J. D. Gatewood, U.S.N.—Detached from the "Kearsarge," proceed home, and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED NOVEMBER 27, 1886.

Williams, L. L., Assistant-Surgeon.—Granted leave of absence for twenty-four days, to take effect when relieved, November 15, 1886.

McIntosh, W. P., Assistant-Surgeon.—Granted leave of absence for twenty-seven days, November 26, 1886.

Norman, Seaton, Assistant-Surgeon.—When relieved, to rejoin station (New York); granted leave of absence for twenty-three days, November 27, 1886.

PHILADELPHIA, DECEMBER 25, 1886.

ORIGINAL LECTURES.

CLINICAL LECTURE
ON LATERAL CURVATURE OF THE SPINE.

Delivered before the Class at the Polyclinic

BY VIRGIL P. GIBNEY, M.D.,
Professor of Orthopedic Surgery in the New York Polyclinic.

GENTLEMEN,—We will devote most of this hour to a study of rotary lateral curvature of the spine.

The definition of lateral curvature is simple enough. The term is usually employed to indicate a deviation of the spinal column to one or the other side. The technical name for the condition is scoliosis. It has been called rotary lateral curvature to distinguish it from simple lateral curvature, a curve which is compensatory. Some cases of lung and pleural disease produce lateral curvature, strictly speaking: they constitute about the only cases in which you have simple lateral deviation of the spinal column. Nearly all cases of lateral curvature are not simple, but rotary in character, and the name itself is a sufficient definition to one who knows the meaning of the words rotary, lateral, and curvature.

The etiology is obscure. It is almost as obscure as that of club-foot. A number of theories have been advanced to account for it by different authorities. Many of these theories are worthless. It is usually observed—and this is the foundation for one of these theories—between the ages of eight and fourteen years. It occurs in boys or girls who work in shops, or in school-children who habitually assume a vicious position while sitting or standing. The patient is usually not brought under the notice of the physician until he has reached the age of twelve or fourteen years. Generally, one feature will be observed in these cases, especially in girls: namely, the projection of one scapula backward and upward. Careful inquiry into the history of such a case will usually reveal the fact that the deformity was observed some time before by the dressmaker and the mother in fitting the clothing; but they probably had explained it on some other hypothesis than that which the physician would accept.

It has been thought by some observers —I give you now the principal theories which have been offered in explanation of the deformity—that in early life, during the rachitic age, as it has been called, when the bones are soft and poorly nourished, the child sustains a fall or a strain, or some other injury, or is carried on one side too much, so that pressure is brought to bear unequally upon the bones, especially upon the articular facets for the transverse processes of the spinal column, in a way to produce slight changes in the planes of these surfaces, so slight as to pass unrecognized; but they become manifest at the age for assuming awkward positions. The subjects of this disorder will then be found, when standing, to support themselves upon one hip, with one leg advanced. At the desk they sit with one leg advanced and the other retracted; one shoulder is more elevated than the other, and the body is twisted. Children with this deformity naturally assume these positions, while others who are healthy will be observed to sit and stand upright, and to have an easy carriage. Children who seek to rest themselves by assuming these awkward positions are objects of suspicion, as they are the subjects who usually acquire lateral curvature. That constitutes one theory of the production of the deformity —*i.e.*, the theory of position. Back of all this, there is in these children a predisposition; and when to this is added the weight of the head and trunk in awkward positions, we have a further cause of the deformity.

I show you here a model of the spinal column, the vertebræ being strung on wire in such a manner that when you press on a spring at the top it causes deflection and rotation, proving that downward pressure is an important element in the production of lateral curvature.

There may be also an asymmetry of the bones. The vertebræ may be ill shaped, just as one leg may be longer than the other. This variation from the normal may be only very slight; but it is not necessary that there should be a marked deformity of the vertebræ in order to constitute a starting-point for lateral curvature of the spine. Having this focus, one articular facet for the transverse process being tilted

down a little, there commences a rotation, and this is further aggravated by the weight of the head and neck, as well as by bad posture in sitting or standing.

The usual age for the occurrence of lateral curvature, as I have said, is from the sixth to the eighth and from the eleventh to the twelfth years; but it has also been observed at the fifth year, and even at an earlier age than this.

The pathology is a rotation of the vertebræ on the vertical axis with a little deflection, giving rise to changes in the general form of the body quite evident during life.

A marked case of the kind I now show you in this girl. You will notice in the lower and middle dorsal region of the spine a curvature, the convexity of which is towards the right, and on that side you will notice that the ribs stand out sharply, while on the opposite side they are flattened. As the patient bends forward, you will notice a prominence of the muscles over the transverse processes on the side of the convexity, while on the left or concave side there is no such ridge at all. That is explained by the fact that as the vertebræ rotate they bring out the muscles on the convex side prominently, while those on the other side are concealed; they are still just as prominent, but are not manifest to the sight. Again, as she bends forward, you can trace the spinous processes down to the point of greatest curvature, and there the muscles stand out so prominently that you lose the processes. Farther down they reappear; but by pressing firmly with your fingers you can find them, even at the point of greatest curvature, but directed towards the concave rather than towards the convex side. There is also a projection of the right scapula, quite marked in this case: it is raised on a higher plane than the other; on the concave side the inferior angle of the scapula stands out much farther from the ribs. On the left side the ilio-costal space is much deeper than on the right side.

It is by making a careful and critical examination, just as we are doing now, that you will be enabled to detect cases at an early date. You will make the patient bend forward; your attention will be called to an absence apparently of a spinous process, no lateral deflection having yet taken place; and it is this point, where, on running your finger down the course of the spinous processes, you find them least prominent, that is the place of beginning rotation. Another early symptom is weakness of the back, especially if the patient be a girl.

This patient has a mine of pathological anatomy in her person. It is a case of old ostitis, or hip-joint disease, subjected to various modes of treatment, and finally to Volkmann's operation, removing a wedge-shaped piece from the neck of the femur, and afterwards to a similar operation below the trochanter minor.

The history of her spinal curvature is this. About two or three years ago, while she was an inmate at St. Luke's Hospital, I was asked to see her with regard to disease of the hips. She had had one hip operated upon; but it was found that the other hip was diseased also. On examination, it was noticed that there was marked lordosis, or a tilting forward of the spine in the lumbar region when an attempt was made to bring the limbs down to a straight position. This led to a careful examination of the spine by Dr. Bull and myself, and we found no deviation whatever; no scoliosis. A little digression here for definitions will be of service. By kyphosis we mean a projection backward, by scoliosis a lateral deviation, and by lordosis an antero-posterior curvature. Those of you familiar with horses have probably seen among them what is called a "sway-back" horse, the animal presenting a marked antero-posterior curvature of the spinal column.

This girl had then a marked lordosis; but no scoliosis whatever was observed. She had this shortened limb and wore a high shoe; but the shoe was defective. It wore out frequently, and she was half her time limping and leaning over to one side. Her present very great deformity in the form of lateral curvature of the spine is due almost entirely, I think, to this shortened limb. And that is a cause of the deformity which I had not spoken about, it being one usually regarded as purely theoretical. But I have now seen two cases of lateral curvature occurring at from twelve to fourteen years of age in patients whose limbs were unequal in length. I have records of the cases, the date of development of the spinal deformity, and I feel sure that no other cause can be found than that of a shortened limb.

So this patient had a shortened limb,

and after disappearing from my view for about a year and a half she returned with this marked deformity of the spine. You can now see to what extent the spine straightens on suspension. By making pressure over the point of greatest curvature and making extension from the hip on the opposite side, I can in some degree lessen the deformity over the correction produced by suspension. You will bear this fact in mind, as it will aid you in the choice of treatment. Suspension shows more plainly the degree of the deformity present, as it raises the left scapula and brings the ribs into prominence.

Another point in the case is atrophy of the right mamma, and this is a very common and a very persistent sign of lateral curvature in the female. There is always atrophy of one breast, which is among the early symptoms in the course of the spinal deformity. If, on examining a girl for curvature of the spine, you find the breasts equal in size, you can question the diagnosis of lateral curvature. Now, as this patient is suspended, you will notice that her whole body is thrown to the right side, and that on the left side there is a deep ilio-costal space, and a very shallow one on the right side.

About six or seven years ago she showed a deformity, the thigh being fixed at an acute angle and strongly adducted, so that the genitals could scarcely be seen. There was also a stiffness of the other hip, which, however, had not attracted much attention. She entered St. Luke's Hospital to have the operation performed known as Volkmann's wedge-shaped operation for the relief of the deformity of the hip. It was performed under antiseptic precautions; the limb was placed in a correct position, and dressings were applied, including the use of the weight and pulley. The patient was kept quiet for five or six weeks, and the result was a very good one. Subsequently I was asked to see her about a tilting of the pelvis forward. What you see now is what was found: a marked lordosis. The left leg was a fair limb, taking it all in all. The right was strongly adducted; there was subluxation at the knee; the hip was locked at an angle. Yet with all the shortening on the right side and this amount of deformity, she could walk about pretty well; and this, it seems to me, is an astonishing feature in her case. There is also present a marked genu-valgum. Nothing was done for her during the early years of her disease except to give cod-liver oil and tonics. She walked about when she could, and remained quiet when she could not walk. She was blistered occasionally over the hips. Then there was a remission of the active symptoms for some time, and she went about by the aid (?) of a spica bandage, but her gait grew worse. Finally, she was quite unable to walk. All this time she had received no mechanical treatment. I had her referred to St. Luke's Hospital for an operation, and then we found some disease also in the left hip; but this hip was not much deformed.

Before proceeding further and speaking of the treatment of this case, I will call your attention to a patient who is in the waiting-room. At our last clinic I was speaking of the necessity of recognizing Pott's disease before marked deformity occurred. This patient has been coming to our clinic for a year or longer. He had chronic inflammation of the knee; his little sister had Pott's disease. They live in Waterbury, Connecticut, and had been in the habit of coming down once in three or four months. The little girl died last summer of some one of the diseases of childhood. When this boy was here on Saturday last, I was taking the plaster off his knee, and at a particular moment I happened to notice his chin resting on the sternum. He was coughing, and the cough seemed somewhat paroxysmal and unlike an ordinary bronchial cough: he seemed to have some distress. I then placed my hand on the back of his neck, and discovered a slight deformity in the cervical region. This, of course, was a very mortifying discovery, but I had not seen the boy since last summer. You will notice two or three of the spinous processes of the cervical vertebræ projecting. He has also a chronic ostitis of the left knee, for which I had been treating him, and on Saturday I also found an ostitis of the right knee. The father has noticed the boy coughing some for the last few months, and for the last few weeks holding his neck stiffly. This case illustrates the importance of always examining the patient thoroughly from head to foot. Sometimes you will find on undressing a seemingly well-formed child a large deformity of the spine,—a knuckle which has been present probably for two or three years. The

joint-symptoms which you may be treating may mask the spinal symptoms, or symptoms of disease in some other joint.

With regard to the treatment of rotary lateral curvature, if you see the patient in the early stages of the disease, before there is much deformity, there being, however, a slight tendency to favor one limb, and slight projection of the scapula, it will be better to treat the case for a while by gymnastic exercises. Observe that I say for a while, and I use the term advisedly. I do not want to convey the idea that you should order a course of gymnastic exercises for the child, and tell the parents to "bring it back in the course of a few months." You should keep a close watch on the patient. It is best to give at first the benefit of gymnastic exercises alone. Let the patient swing on a parallel bar while resting on his hands, allowing the weight of the lower limbs to straighten the spine; or he can use dumb-bells, or go through almost any other exercise which you can readily devise, and which will bring the muscles into play equally. Developing the muscles and placing the child in a better state of health will at the same time tend to correct the deformity. Then you should caution the mother and the patient about those awkward positions before alluded to. The child should have a chair made especially for its use: it should be just as high as the distance from the popliteal space to the bottom of the foot; its depth should be equal to the distance from the coccyx to the popliteal space,—that is, a good, generous chair, neither too high nor too low. It is also a good plan for the parents night and morning, when the child is nude, to correct the deformity themselves. If the gymnastic exercises can be made a matter of pleasure, by the addition of music or other means, it will be all the better. These exercises should be practised for two or three months under the guidance of the physician. If he finds, then, that there has been no change in the deformity, or that there has been an increase, he should lose no time in employing an apparatus. The apparatus is not intended to correct the deformity, but to prevent further deformity. Self-suspension by means of one of these swings or by pulling one's self up on a horizontal bar will bring the spine into a straight line, and then any apparatus which will hold it so, whether made of steel, felt, or other material, will be a good brace. I am in the habit of using almost exclusively the plaster-of-Paris corset, for the reason that I renew it every two or three months. It fits perfectly: I can trim it out where it chafes, and when it begins to crumble or break down it is time to make another jacket in order to get an improved position. The child having been exercising all that time, I expect to get an improvement in position every time I renew the jacket.

It has been objected to the plaster jacket that it produces atrophy of the muscles and thus retards any corrective process in the spinal column. This presupposes that the deformity is partly muscular, and that the muscles must be fully developed in order to prevent deformity. But that theory has long since been abandoned, and the deformity is now looked upon as being due to a change in the bone,—not a morbid process especially, but simply pressure brought to bear upon certain processes which cause tilting and rotation. The jacket might produce a certain amount of atrophy in the muscles if it were worn all the time, but it is not worn at night. It is taken off some time before going to bed, kept off during the night and for some time in the morning, and the child then is induced to take exercise which it would not take voluntarily throughout the day. As the jacket is not worn at night, the muscles have opportunity to grow, and in the recumbent posture the spine is nearly straight.

About half of the cases in this country and in England are treated without any apparatus. Some system of exercise is usually adopted. Mr. Bernard Roth, of London, has a system of twelve or fifteen different movements through which he puts patients. The patient lies prone upon the floor and goes through these various movements, and during a part of the exercises the physician's foot rests upon the patient's pelvis. As I have witnessed the procedure, it is quite an amusing spectacle. It is rather embarrassing for a young lady to go into a doctor's office, bare herself down to the hips, lie prone upon the floor, twist herself around like a serpent, and bring herself up on all fours with the doctor's foot on her pelvis. There is still a certain amount of modesty left in all classes of society, and the method seems objectionable for this reason.

In the later stages, where deformity is pronounced, bony changes have taken place and the ribs project, and such cases defy nearly all treatment. It is for these cases that the different forms of apparatus have been constructed. One of these apparatuses is that used at Forty-Second Street Hospital. It consists of a frame with a leather plate on the side of the convexity where it makes pressure. Dr. Taylor uses his spinal assistant modified, and Dr. Shaffer also has a modified apparatus of the same kind with a pelvic band. To show how inefficient this system of pressure upon the convexity of the spine is, you can press upon the projection with your hand and it will be apparent that by so doing you only flatten or press down the ribs and bring them in closer contact with the spinal column. If a means of pressure could be devised by which the deformity could be unrolled, the spinal column untwisted and brought around into its correct position, the pressure might prove of some benefit in correcting the deformity. But no one of the fixed forms of apparatus with which I am acquainted accomplishes this object. In a hospital in Great Britain I saw a bed or frame by which it was attempted to squeeze or press the patient into shape: an immense lever- or screw-power is brought to bear with this object in view.

For the treatment of a case of rotary lateral curvature of the spine you should have a suspension apparatus like the one here used, the ordinary tripod and swing; next learn what faulty positions your patient is in the habit of assuming, and correct them, attending at the same time to the general health. If the patient can go into the country, so much the better. I have very seldom seen cases of lateral curvature developed outside of cities, though I have seen a considerable number of cases from country towns and from the suburbs of larger towns, as well as from cities. In cases of slight deformity, obedience to general instructions has succeeded in correcting the condition. But in a case of this kind you cannot hope to correct the deformity beyond a slight degree, but you may hope to put the spinal column into better shape by suspending the patient and maintaining the position thus assumed by means of apparatus. When the jacket is off I will have the parents practise this movement twice a day; that is, with one hand in the axilla grasping the left shoulder, and the other over the ribs of the projecting side, make passive movements for ten or fifteen minutes as if attempting to untwist the rotated spinal column, then let the patient hold on to the end of the table or head-board of the bed on which she is lying, while traction is made on her pelvis. This is hard work; but I have seen benefit result from it. Electricity is often employed, applying the electrodes over the convex side. I think the faradic current tends to develop the weak muscles of this side.

Now as to the plaster jacket. In the first place, the patient must have a seamless, skin-fitting merino shirt, long enough to serve as an outside covering for the corset when doubled back upon it. These shirts are made to order at two different places in this city, on receipt of the following measurements: the circumference of the chest, of the loins, of the hips, and double the distance from the top of the shoulder to the trochanter major. The shirt should be put on wrong side out. Use good plaster of Paris (and, let me remark, there is none better than the S. S. White Company's dental plaster: it comes in six-quart cans, and is convenient for use). As to the roller bandage, I think smooth crinoline sized with starch is preferable. The roller may be two and a half inches broad and six or more yards long. The mammæ can be protected with some cotton batting, and a folded towel can be placed in the space under the scapula on the concave side. The best dinner-pad is a full dinner just before applying the jacket. You then should have the meshes of the crinoline bandage filled with the plaster of Paris, and when ready to begin the application the bandages should be placed in warm water. It is not necessary to put salt or other material into the water to hasten the drying of the jacket: these agents merely tend to crumble the plaster and cause the jacket to break down.

As you apply the bandage, wrapping it in successive layers around the patient's body, let an assistant follow you, rubbing and smoothing it down with both hands. Then place a little cotton pad or soft felting over the salient points; otherwise the patient will complain of its chafing. Here, for instance, is a salient point over the coccyx, and another over the ilium, near the anterior superior spinous process, and at each of these places I lay a little

cotton. If the jacket is not made comfortable and well-fitting, your practice will tend to bring this system of treatment into disrepute. After applying the jacket, and waiting until it has sufficiently dried, you cut it down the front with a pruning-knife, and wait again until it has still further hardened. You can now take the jacket off, trim the top and bottom, under the axilla, and over the crest of the ilium, but do not take off too much,—only a sufficient amount to make it even. Then lay it aside until the next day, when the patient should again visit you. Let the patient wear a skin-fitting shirt, and, while partially suspended, you can apply the jacket and secure it with a roller bandage. Trim at the points where it chafes, top and bottom, in order to secure a perfect fit. Let the jacket project well down over the pubes. Dry the rude corset for twenty-four hours over a range, having it covered with paper, but turning it over two or three times during the drying process; that will make it hard and tough. Then turn the shirt over at the top and bottom and sew it, and trim the edges with chamois or moleskin. Finally, with an awl and a strong thread, fasten a strap with shoe-hooks up the front, and you will have a strong, neatly-fitting jacket.

ORIGINAL COMMUNICATIONS.

REPORT ON RECENT PROGRESS IN THERAPEUTICS AND MATERIA MEDICA.

BY FRANK WOODBURY, M.D.,

Professor of Materia Medica and Therapeutics and Clinical Medicine in the Medico-Chirurgical College of Philadelphia, etc.

THE ACTION AND THERAPEUTICAL VALUE OF VEGETABLE ASTRINGENTS.

THE vegetable astringents in common use owe their value to the presence of tannic acid; but the chemical composition of the tannic acid is not identical in all, the variety being designated in each case by a prefix indicating the source, as kino-tannic, catechu-tannic, etc. They all, however, have in common the property of precipitating albumen and gelatin from watery solution, and of converting raw hides into leather. In addition, they produce an astringent taste in the mouth, and give color-reaction, green or blue, with persalts of iron. The different varieties do not exert exactly the same effects, partly because they exist in different combination, but further because they seem to have different powers of precipitating albumen.

Gallic acid differs from the foregoing description in several important particulars. It does not precipitate albumen or gelatin; it does not tan; and its astringent taste is hardly perceptible.

Pyrogallic acid, while also capable of precipitating albumen, differs widely in most other respects from tannin.

From experiments made in the laboratory of the University of Edinburgh, Dr. Ralph Stockman* was led to the following conclusions:

Gallic Acid.—Either when locally applied or after absorption into the blood, gallic acid evidently exercises no other action than that of a weak inorganic acid, and certainly has no claim to any special action as an astringent. The only action which it can have in this direction is the power which it possesses, in common with all other acids, of diminishing the alkalinity of the blood, and thereby increasing its tendency to coagulate. Stronger acids, however, will act much more powerfully in this direction than it does. Any influence in lessening the calibre of the blood-vessels, either by peripheral or central action, must be denied to it. When locally applied, the fact that it does not precipitate albumen must prevent its having any influence on a catarrhal inflammation.

Tannic Acid.—Locally applied, its action for good depends on its power of precipitating albumen, the layer of tannate of albumen which is formed acting as a protective to the underlying mucous membrane. To this action is due its value in catarrhal inflammation of the alimentary canal and in discharging surfaces generally.

The experiments have shown, however, that its usefulness is limited to such cases, and that as a remote astringent it is valueless. In weak solution and uncombined, its action on contractile tissues, such as the vascular walls, is simply that of a dilute acid, while it is only when stronger solutions are used (much stronger than can

* Report to the Scientific Grants Committee by Ralph Stockman, M.D., read in the Section on Therapeutics at the Meeting of the British Medical Association at Brighton.—*British Medical Journal*, December 4, 1886.

ever exist in the blood, even if it were not in combination there) that its power of precipitating albumen comes into play. When its chemical affinities have been satisfied by neutralizing it with a base or with albumen, it is no longer capable of precipitating albumen, and exercises, therefore, little or no influence on the parts with which it comes in contact.

Independently of these considerations, the very small quantity in which it exists at any one time in the blood, and that in combination, must also militate against its having any remote action. As we have seen, the only channels of excretion besides the bowels are the kidneys, and hence it is hardly possible that it can have an astringent action on any of the other mucous membranes, such as the bronchial. It is now almost an axiom in therapeutics that substances which do not possess a very decided general action can affect only those mucous membranes by which they are excreted, and it is improbable that tannin is any exception to this.

With regard to its action on the kidneys, it is conceivable that it may have a favorable influence in diminishing albuminuria, but even this is to be regarded as doubtful. Many eminent clinicians have expressed disbelief in its value, and the only cases which the reporter had been able to find, in which the amount of albumen was carefully estimated from day to day, tend to confirm this view.—(Cases of Briese, *Deutsches Archiv für Klin. Med.*, 1883.)

[In the four cases referred to reported by Briese the administration of the tannate of sodium for long periods had no influence either on the amount of urine or the albumen present in it. It will be noticed that Dr. Stockman has previously declared that when its chemical affinities are satisfied with a base it exercises "little or no influence on the parts with which it comes in contact." It is difficult to understand why the results from the tannate of sodium were considered as warranting the conclusion that tannic acid is ineffective in cases of albuminuria to reduce the amount of albumen. Clinical evidence is not wanting that tannic acid is useful in nephritis, reducing the proportion of albumen and favorably influencing nutrition.]

PIPERINE IN OBSTINATE INTERMITTENTS.

Dr. C. S. Taylor recommends piperine as an excellent addition to the treatment of malarial attacks, especially when they resist the use of quinine. In an obstinate case he gave three grains of piperine every hour for six hours, and on the following day the same quantity every three hours. As soon as the paroxysms were checked he gave—℞ Pilulæ hydrargyri, gr. j; piperinæ, gr. ij; quininæ sulphatis, gr. iij, morning, noon, and night, for a few days. Should the second paroxysm be escaped, the following pill was ordered every third hour: ℞ Piperinæ, gr. v; mucilaginis acaciæ, q. s. M. It is now three years since the above patient was treated, and she has continued free from the malady.

In another case, one of congestive chill, five grains of piperine were given at once, followed by brandy and champagne, and the patient was directed to be wrapped in blankets and external heat applied. Afterwards full doses of the aromatic spirit of ammonia were given every third hour, and the champagne was continued. When reaction was established, and the sweating-stage began, five grains of piperine were ordered every two hours and continued for four days; subsequently a grain of blue mass was added to each pill, and a saline purgative given. The patient's health was perfectly restored. Patients sometimes object to quinine on account of its affecting the head, but no such effect was observed from the piperine, although it is a powerful stimulant, carminative, and febrifuge.—*British Medical Journal*, September 4, 1886.

PIPERONAL.

Piperonal, an aldehyde corresponding to piperonilic acid, is obtained by the oxidation of piperine. It forms small, white, prismatic scales, and possesses a strong odor of vanilla; a small quantity placed upon the tongue produces a sensation analogous to but more persistent than that caused by mint. It melts at 125° F., and at a higher temperature volatilizes completely. When ignited it burns with a flame and smoke like those of camphor. It is insoluble in cold water; in hot water it melts and appears like drops of oil; it is readily soluble in alcohol and in ether. According to Frignani (*Giornale Internazionale delle Scienze mediche*), it possesses both antipyretic and antiseptic properties, which, while not very decided, are yet in many cases sufficient. It has been given in fifteen-grain doses repeated every two

hours or three or four times a day. The most noteworthy disagreeable effects are nausea, eructations, and dryness of the throat. As an antiseptic piperonal is very efficient, and will no doubt take high rank among other agents of this class.

SANDAL-WOOD OIL IN URETHRITIS.

The general indifference or distrust of oil of sandal-wood is apparently due to the fact that, owing to its high price, it is extensively adulterated with copaiba or castor oil. The pure oil is clear, light yellow in color, and very pungent on the tongue, with a characteristic odor. When tested (Dragendorff's test) with a five-per-cent. solution of bromine in alcohol, if a few (ten to fifteen) drops of this test be mixed with one of the oil, the color becomes a brownish violet, and later on a dark blue. Dr. Letzel, of Munich, has communicated (*Allg. Med. Central-Zeitung*, Nos. 76–78, 1886) the results of his experience in the treatment of gonorrhœa with this agent. He used gelatin capsules, two or three of which, each containing five minims of the oil, were taken three times a day. Of ninety-seven patients thus treated, four had gastro-intestinal disturbance: two of these had violent diarrhœa, and the other two severe dyspepsia. Eructations and burning sensations in the stomach were often noticed in the rest, but the drug was persisted with. It should not be given on an empty stomach. One bad symptom, which occurred in five cases out of the whole ninety-seven, consisted in severe pains over the kidneys. It is better tolerated, however, than copaiba. The results were:

1. Given in an early stage, the secretion diminished rapidly and the pain on micturition ceased,—this in thirty-seven out of forty-two cases.

2. If, after ten or twelve days, the oil be discontinued, the old symptoms reappear.

3. The best results were obtained when the oil was commenced in the third or fourth week of the gonorrhœa, together with the use of weak astringent injections.

4. Cystitis and gonorrhœal prostatitis were always greatly benefited by the oil.

5. Cases of gleet did best under local treatment.—*British Medical Journal*, December 4, 1886.

THE USE OF OXYGEN-INHALATIONS IN PULMONARY PHTHISIS.

The chemical and some of the physiological relations of oxygen are beginning to be discussed, though they are not yet properly appreciated, by the masses. This has been partly brought about by the advanced state of popular scientific education and partly by the persistent and elaborate advertising in the secular press, not omitting religious and scientific journals. It is known by intelligent people that various "oxygen cures" and "home treatments" are purely commercial enterprises; and yet this form of treatment has become so popularized that physicians are beginning to give oxygen by inhalation a trial in chronic pulmonary affections under strict scientific conditions. Dr. Wallian (*Medical Bulletin*), in a paper entitled "Suggestions to Oxygen-Users," calls attention to several sources of failure which may cause disappointment and bring this method into unmerited disrepute. These are: (1) impure gas; (2) want of discretion in the selection of cases; (3) injudicious exhibition; (4) neglect to regulate the personal habits of the patients; (5) failure to enlist rational and necessary auxiliaries; and (6) want of due perseverance. He recommends the use of pure chemicals and the manufacture of the gas as required. The temperature employed to generate the gas should not be excessive. The gas should stand over fresh water for twenty-four hours before being used, and then passed through a series of wash-bottles, first through solutions of potassium permanganate (℥j ad C.j), and caustic soda or potash, and finally through several bottles of pure water. Three cardinal points are mentioned as being important in the administration as contributing to the success of the treatment: (1) See that the patients breathe properly by thorough inflation of the lungs. (2) See to their diet; select a regimen carefully, combining all the essential food-elements in due proportion and at the same time attractive and appetizing to the patient. Improve nutrition. (3) See that the functions of the skin are maintained by baths. Finally, quiet the apprehensions of the patients, and teach them to be content with slow progress in removing diseased conditions and restoring normal functions.

LIQUOR MAGNESII BROMIDI.

The following is used as a sedative in the Philadelphia Hospital. Add to acid hydrobromic, dilute, f℥xvj, sufficient magnesium carbonate to neutralize it (about a

troy ounce will be sufficient). Each teaspoonful will contain nearly seven grains of anhydrous magnesium bromide. The advantages are that this is easily prepared; that it contains more combined bromine than any other bromide (with the exception of lithium bromide); that it is constant in strength, and that its cost is moderate. —Joseph W. England, Ph.G., *American Journal of Pharmacy*, November.

COCAINE.

Marvellous cases are reported in the journals of cocaine-poisoning from moderate doses of cocaine, and a death of an adult has been attributed to painting the larynx with a two-per-cent. solution.* On the other hand, Dr. Hammond claims to have taken eighteen grains hypodermically without serious effects. It is used in Dr. Da Costa's wards at the Pennsylvania Hospital as a stimulant for cases of nervous depression and weak circulation in low fevers, a half-grain having been given every two hours for several days in cases of typhoid fever, followed by recovery.

ERGOT IN PARTURITION.

The use of ergot in labor has been the subject of a controversy which has led to many heated discussions in our medical societies, and notably the American Gynæcological Society. The whole question is well summed up by Dr. Thad. A. Reamy in a paper entitled "Ergot in Labor and Puerperal Convalescence, with Protests against the Extent to which it is Employed," read before the Cincinnati Academy of Medicine, November 22, 1886.† Dr. Reamy's conclusions are as follows:

1. Ergot may properly be administered in small doses, say ten to twenty drops of Squibb's fluid extract, before delivery in cases of uterine inertia which resists other means, and especially in women who are predisposed to hemorrhage.

2. It should be administered in full doses hypodermically, or per os, or both, in cases of post-partum hemorrhage.

3. When an anæsthetic has been freely used during the second stage of labor, it to some degree predisposes to post-partum hemorrhage: ergot is therefore indicated.

4. It should be administered in small doses two or three times daily during the period of puerperal convalescence, whenever a flabby uterus indicates it. In such cases there is no better combination than the pill recommended by Mundé:

℞ Ext. ergot., gr. j;
Quininæ, gr. j;
Ext. nucis vomicæ, gr. ¼. M.

* Case of Dr. W. H. Long's, United States Marine Hospital Service, reported in the *American Lancet*, November, 1886.

† Cincinnati Lancet-Clinic, December 11, 1886.

THE OCULIST, THE OPTICIAN, AND THE PUBLIC.

BY L. WEBSTER FOX, M.D., AND GEORGE M. GOULD, A.B.,
Philadelphia.

IT has in all civilized countries been found not only conducive to the public good, but also necessary to the public welfare, to limit the traffic in drugs to such persons as have pursued a special course of study fitting them to dispense the materia medica intelligently, and who are in other respects qualified to deal wisely in matters which are of so highly important and delicate a character.

It is our conviction that the business of supplying the community with spectacles is, in its way, and to a degree, a function of as profound importance to the community at large; that at present this office is shamelessly prostituted to money-making; and that similar legal restrictions should be set about it as have been found beneficial in the case of drug-selling. Our contention is that the optician should be placed on precisely the same legal standing as the druggist,—that is, he should by education, both general and technical, and by the restriction of his duty to his legitimate function, be placed before the community with a guarantee by the proper authority that he is qualified to do what he pretends to do, and that he shall not pretend to do what is wholly beyond and outside his province.

Just as the druggist *quâ* druggist is not a physician, so should the optician not pretend by his practice to be an oculist. If the professions of medicine and pharmacy are distinct, it is beyond all cavil that the profession of ophthalmology is quite as different from that of manufacturing and selling optical instruments.

We speak thus strongly because the reason for the faith that is in us is derived from the memory of a long series of cases where irreparable injury and years of suffering have been the result of the common foolish habit of sufferers from eye-troubles

relying on the optician—respectable or quack—to do the work they should have been legally protected from seeking or getting, or, yet more correctly, from being deceived in the getting.

In our hospital practice, especially, these cases continually occur, but in the best private practice also we meet with them constantly. Such instances had at last grown so striking and frequent that we began inquiring if our experience was exceptional, or if that of other physicians was at all similar to our own. We asked a half-dozen of our friends what their experience had been, and, with their consent, we publish the following excerpta:

Dr. Swan M. Burnett, of Washington, D.C., says, "I am sure a great deal of damage has been thus done. I know an optician who fits people with glasses with which they can see both far and near. Some of these people I have seen, and I have found that he adapts one eye to distant vision and the other to near! It must be a very vigorous person who can stand that long."

Dr. Henry Dickson Bruns, of the editorial staff of the *New Orleans Medical and Surgical Journal*, says of the better class of opticians, "Having a good knowledge of physical optics, they soon come to believe that they understand the whole science and art of 'refraction.' Hence their lamentable mistakes."

Dr. D. B. St. John Roosa, of New York, writes us, "Like yourselves, I have seen some bad results from the custom of certain opticians prescribing spectacles. When they do, they generally make a muss of it. I have known them to prescribe glasses for glaucoma, for myopia when the patient was hypermetropic, etc."

Dr. D. Webster, of New York, says, "I heartily join you in your protest against the prescribing of spectacles by opticians. I consider it on a par with counter-prescribing of medicines by apothecaries. There are a number of peripatetic venders of spectacles who go about through the country telling the unwary that they are students of Dr. C. R. Agnew and personal friends of his, and that they are endorsed by him. Some of these men impose upon the credulity of those who might easily be better informed, and obtain from them almost fabulous sums of money for spectacles that are of very little value. . . . Although I have, as every one who has much to do with examining eyes and fitting them with glasses must have, seen cases like those you refer to, where the eyes have undoubtedly been injured by wearing absurdly wrong glasses, yet our cases are not so indexed that I can readily look up their records; therefore I hope you will be content with generalization."

Dr. Dudley S. Reynolds, of Louisville, Kentucky, editor of *Progress*, kindly sends us a valuable and interesting list of cases. We regret that we cannot quote the details. We give synopses of the more important.

A law-student came to him "wearing $-\frac{1}{7}$", prescribed by an itinerant optician. Study had become impossible, owing to severe headaches, photophobia, and sundry distressing neurotic symptoms. Rest under a mydriatic gave relief, and a proper correction of his *mixed astigmatism* enabled him to resume his studies with a perfect reinstatement of health.

A poor young woman bought several pairs of high minus spherical glasses from a jeweller, who undertook to refract her eyes with a machine "just such as used by distinguished oculists." After great ocular injury from the spectacles, she was found to be *highly astigmatic*. Proper correction relieved her of the intense ciliary neuralgia from which she had suffered, and arrested the progress of the posterior staphyloma and of the amblyopia.

Dr. Reynolds further says, "I fully realize the importance of exposing as far as possible the dangerous practice of travelling spectacle-peddlers and common jewellers attempting to adjust glasses for the correction of optical defects. My note-books are full of such cases, and I know of no evil which more urgently demands the general attention of both the public and the profession. I might cite other cases almost equally striking which resulted from attempts to determine and correct refraction by the aid of the ophthalmoscope alone."

We had intended citing a number of our own cases in detail, but are warned that our limited space forbids, and we must with regret omit them. We willingly give way to the unexpectedly full replies our friends have so courteously sent us, and are only sorry we felt compelled to curtail these so much. We cannot leave the subject, however, without referring to a recent case. It was that of a lady past 55, who relied on the optician to fit her with

"old age" spectacles. Her dimness of vision, however, was only temporarily benefited by the spectacles, and they were soon changed by the obliging dealer. But there was before long a dimness of vision, and again a change. Finally, after many changes,—we forget how many,—and when the precious time of possible relief had been wasted, the patient came under observation with a typical glaucoma chronica, wholly beyond cure. No astigmatic correction had been added to the presbyopic glasses; and, if not absolutely induced, it is far more than probable that the glaucoma had been increased and its progress hastened by the irritation resulting from the glasses. At least,—and this is the most important,—the patient's reliance on the optician cost her the terrible penalty. Had the law directed her to a physician, as it does in other forms of illness, no such result would have taken place. No optician ever thinks for a moment of any but refractive errors, and, of course, not of the remote bearings of a supposed correction of these. Indeed, it may be added that perhaps many oculists are far from properly appreciating the persistently intimate co-relations of the errors of refraction (with their correction) and general ocular and cerebral disorders. So that it is no exaggeration to say that in writing a prescription for glasses, the judgment must be guided by a multitude of considerations that only the physician plus the ophthalmologist can for a moment be supposed to consider and estimate aright. How far soever from perfection the oculist may be critically adjudged, there can be no question that the peddler, the jeweller, and often the optician are yet farther from it, and that some legal process of culling and gleaning in this field would be a great benefit to the community.

1304 WALNUT STREET.

THE ELECTRO-DIAGNOSIS OF NEURITIS AND ANTERIOR POLIOMYELITIS.

Read before the Philadelphia Neurological Society

BY JAMES HENDRIE LLOYD, M.D.,
Instructor in Electro-Therapeutics in the University of Pennsylvania.

THE irritability of a nerve-trunk to an electric current (either by galvanism or faradism) depends upon the integrity of the axis-cylinder. This integrity may be impaired by pressure upon or by a fracture of the axis-cylinder. The pathology of degeneration in a nerve-fibre is, first, an increase of protoplasm about the nucleus in the sheath, then the splitting up of the white matter, and, finally, the breaking of the axis-cylinder.* In neuritis it may be a question how soon this *fracture* takes place, but *pressure* evidently occurs very early, and in severe acute neuritis (as in some forms of facial paralysis) this pressure is very great, is very quickly established, and, in the worse forms, no doubt leads to the breaking of the axis-cylinder. If electro-irritability, therefore, be retained in the nerve in neuritis, it must be either because the pressure is very slight or else because of an escape of some nerve-fibres amidst the destruction of others. The first event is what happens in mild subacute neuritis, but the latter alternative does not seem very probable when the disease is interstitial in the narrow calibre of a nerve-trunk, and especially when it has continued a long while. On the other hand, in anterior poliomyelitis of slow progress the large cells may be gradually and successively destroyed, followed by the degeneration of a comparatively few nerve-fibres; and in these cases the nerve will retain its electro-irritability (possibly diminished sometimes) although the muscles may have commenced to put on the modal and serial changes of degeneration. These facts have been long recognized, but do not appear of late to have been sufficiently relied upon as a possible factor in diagnosis.

De Watteville has drawn a distinction between myotrophic and neurotrophic centres in the cord, but the distinction, as well as his illustration, is artificial, and the phenomena probably depend upon the extent of degeneration and the number of nerve-fibres involved. His own opinion inclines to the view that where nerve-irritability (especially faradic) is preserved, especially in cases otherwise chronic, with muscular atrophy and muscular reactions of degeneration, we have a condition rather of atrophy of the anterior horns than of the nerve-trunks, affording strong corroborative evidence in establishing the differential diagnosis. It is this condition of retained nerve-irritability, with degeneration-reactions to galvanism in the muscle, which we have in such slow cord-lesions as

* Rauvin, as quoted by Gowers in "Diseases of the Nervous System," Part II.

amyotrophic lateral sclerosis and chronic anterior poliomyelitis. Here other symptoms aid the diagnosis, especially the large fibrillary contractions in the muscular atrophy and the spastic symptoms in lateral sclerosis. The only forms of neuritis that he knew of in which faradic irritability of the nerve is preserved, with muscular reactions of degeneration, are essentially mild, non-chronic attacks (such as mild facial palsy), and in these the lesion is probably light compression, leaving the axis-cylinder unbroken.

It must be recalled that muscle-tissue alone will not respond to such strength of faradism as we use upon it in the clinic, but is excited through the motor-nerve-endings in its tissue: consequently when we have response in a muscle to faradism we infer that the nerve is still intact or partially so. Hence in severe facial palsy one of the first symptoms is loss of farado-contractility.

Illustrative cases have been noted as follows:

1. A very marked case of chronic anterior poliomyelitis, in which both legs and arms were involved, with very great fibrillary contractions. Very exact notes of this case have been preserved, and show that while the affected muscles showed the slow, lazy contraction of degeneration, with slight changes in the normal formula, yet the nerve-trunks remained normal (or only slightly decreased) to faradism. This is just the condition which would be expected in anterior poliomyelitis, but we would not expect it in neuritis.

2. In this case there was a rapid wasting of certain isolated groups of muscles,—as deltoid, infra-spinatus, and supra-spinatus (possibly biceps and supinator longus),—and with muscular reactions of degeneration there was rapid loss of nerve-irritability to faradism. This loss of farado-irritability, with absence of fibrillary contractions, also the circumscribed group of muscles in which it occurred, was rather suggestive of a neuritis destroying first the nerve-trunk.

3. A case of rapid and complete wasting of the muscles especially presided over by the nerves which are stimulated at Erb's motor point: deltoid, spinati, biceps, and supinator longus. Nerve-irritability to both currents abolished; reactions of degeneration in muscles followed by loss of muscular irritability (except slight modal response); no fibrillary contractions; history of traumatism. All the symptoms as well as the history point to a neuritis of a few nerve-trunks in the plexus, and the electric examination confirmed this.

4. A marked case of facial paralysis with secondary contractions, with *total* abolition of nerve-irritability to both currents and reactions of degeneration in muscle. This is a typical picture of a neuritis.

5. A case of amyotrophic lateral sclerosis (descending degeneration?) with spastic muscles, wasting and exaggerated reflexes. The nerves respond normally to both currents,—showing certainly not a neuritis,—while there are slight reactions of degeneration in the muscle. Cases somewhat like this have been reported by Hughes-Bennett.*

Conclusions.—The point sought to be emphasized is the retention of electro-excitability in the nerves, which in chronic cases does not appear consistent with the idea of a neuritis, but, rather, of a slow cord-lesion. If this electric excitability can be preserved in a chronic neuritis, we must suppose a very slow interstitial inflammatory process which compresses some fibres and allows others to escape. But to think that this happens in the narrow calibre of a nerve-trunk during a prolonged period of inflammation seems to require some effort of imagination and credulity. The electrical reactions in the above cases (especially the condition of *nerve*-irritability) support the other symptom-groups in their significance as to a cord- or a nerve-lesion.

Walnut and Fortieth Streets.

HÆMORRHOIDS TREATED BY INJECTIONS OF CARBOLIC ACID.

BY G. H. DAVIS, M.D.,

Black River, New York.

TWO cases of successful use of carbolic acid by injection in the treatment of hæmorrhoids have recently occurred under my care.

C. B. came to my office June 10, 1886, to be treated for piles, which had troubled him for more than thirty years. Upon examination, I found in the rectum a vascular pile, which bled freely upon being punctured with the aspirator-needle. He also had a bad rectal fissure. After introducing the speculum,

* Treatise on Electro-Diagnosis.

I injected the pile with twenty minims of a fifteen-per-cent. solution of carbolic acid. I also cauterized the fissure with solid nitrate of silver, and instructed the patient to use as an enema the fluid extract of hamamelis, one drachm to the ounce of water, every morning.

At the expiration of one week he returned. I found the hæmorrhoids much reduced in size and less vascular. The treatment was repeated, and the same injection used as before.

He did not return to the office again until three weeks had elapsed. I now found that the hæmorrhoidal tumors had entirely disappeared, and that the fissure had nearly healed. I again applied caustic to the fissure, and ordered an ointment as follows:

℞ Ext. belladonnæ alc., gr. v ;
Acidi carbolici, gr. x ;
Plumbi acetatis, ʒij ;
Petrolati, ʒvi.

M. S.—To be used night and morning.

On July 21 the patient again returned. I found the fissure entirely healed, and no traces of the hæmorrhoids. He was discharged, with instructions to return again in case there should be any indications of a return of the trouble. I have kept the case under observation until the present time,—about three months,—and there have been no indications of a relapse.

The patient now works hard at heavy labor every day, something he was unable to do before.

F. C., laborer, age 58 years, came to my office August 8, 1886, to be treated for hæmorrhoids and chronic diarrhœa, from which he had suffered since leaving the army in 1862. The same treatment was used in this case as in the preceding one, and the patient instructed to return in two weeks. He returned August 22, and upon examination I found the hæmorrhoids much reduced in size. I again injected them, using thirty minims of the solution of carbolic acid. He was to return again in two weeks, but failed to appear until September 12, when he called to tell me that he was cured and had gained ten pounds in flesh since the first treatment. I examined him, and found only slight evidences of hæmorrhoids, which he would not permit me to inject, saying that he was well and did not need further treatment.

Up to date he has had no return of either trouble. Curing the piles seemingly cured the diarrhœa.

I report these cases so as to call the attention of the profession to the value of the local treatment of hæmorrhoids by hypodermic injections of carbolic acid.

The speculum used was O'Neal's bivalve, and the injector an ordinary hypodermic syringe with a long aspirator-needle. My examining-table is made in two parts, set at right angles, each part being three feet in length when fitted together.

The patient lies on the right side, which renders examination easy, with very little exposure of person.

I have other cases under treatment, which will be reported at some future time.

TRANSLATIONS.

Polarized Currents.—At the Paris Biological Society, MM. Onimus and Larat have recently presented a series of tracings which described the contractions produced in the muscles of a frog's leg by means of polarized currents from the human body.

A first series of experiments consisted of galvanizing ordinary water and passing the currents determined by the electrolysis of this water through the gastrocnemius muscles of a frog's legs. MM. Onimus and Larat noted, at the moment of the contact and interruptions of the current, a series of sharp muscular shocks, analogous to those produced by a direct current. In a second series of experiments, the authors applied the electric current to one of their own limbs, and by obtaining the secondary current of polarization thus engendered in the substance of the tissue they likewise produced contractions which lasted some instants after the cessation of the direct current.

This statement is an irrefutable confirmation of the opinion of Matteucci, Becquerel, Legros, and Onimus, concerning the manner in which electricity acts upon living tissues; it also demonstrates the reason why the theory of electrotomy maintained by Erb, Dubois-Reymond, and the entire German school is erroneous.

Physiological Action of Ordinary Piperidine.—At a recent meeting of the Biological Society, MM. Oechsner de Connick and Pinet communicated the result of their experiments concerning the action of ordinary piperidine on warm-blooded animals. A series of eight experiments on guinea-pigs showed that no appreciable distance exists between the action of hexahydrure of pyridine and that of ordinary piperidine. The same process was resorted to as with cold-blooded animals. Subcutaneous injections were made of alkaloid, pure or with the addition of water.

PHILADELPHIA, DECEMBER 25, 1886.

EDITORIAL.

ONE YEAR'S WORK OF THE STATE BOARD OF HEALTH.

THE first annual report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania was transmitted to the Governor of the State December 7, and has just been issued in suitable form. As the youngest of the departments of our State government, the Board has naturally been compelled to defer to all the others in the matter of priority in the publication of its annual report, and it may thus appear to have been unnecessarily tardy in its compilation. Very few of the reports of other State Boards of Health for the corresponding year, however, have appeared in advance of our own. It constitutes a volume of three hundred and fifty-six pages, with eight full-page maps, two large maps, six charts, six plans, two wood-cuts, and twenty tables, with an index. It was the aim of the Executive Committee to make it the vehicle not only of permanently recording the official actions of the Board, but also of bringing together such other information in regard to the sanitary condition of the State as might indicate the urgent necessity for more extended effort to improve it, especially in the important direction of checking the pollution of rivers, now almost entirely unprotected, and also of placing before municipal authorities throughout the Commonwealth the results of the experience of the metropolis of the State as a guide to them in arranging the details of sanitary organization and reform.

The history of the Plymouth epidemic of typhoid fever, comprised in three valuable papers,—the first by Dr. Pemberton Dudley, a member of the Board, tracing it to its origin in the city of Philadelphia; the second, by Dr. Lewis H. Taylor, of Wilkes-Barre, detailing its rise and progress, and pointing out its local cause by a process of inexorable logic; and the third, by Dr. Morris Stroud French, of Philadelphia, one of the physicians sent by the Citizens' Relief Committee of Philadelphia to aid the terror-stricken inhabitants, accurately showing the amount of the expenditures incurred in the care of the sick,—"constitutes," in the language of the Secretary, Dr. Lee, "at once a most valuable contribution to the history of epidemics and an irrefutable argument in favor of immediately instituting a thorough sanitary organization throughout the State, and of jealously guarding all sources of public water-supply, as measures of simple economy, entirely apart from any humanitarian consideration."

The Secretary also congratulates the Board on the harmonious manner in which it has been enabled to work through, and side by side with, local boards of health wherever the public health has been so seriously threatened as to call for its interference. So far from any feeling of petty jealousy having manifested itself on the part of local authorities, the officers of the Board have been welcomed with open arms, and their advice gladly accepted and promptly acted upon. To this fact it is doubtless to be attributed that several very promising epidemics of typhoid fever which might have repeated the sad story of Plymouth (such as those at West Elizabeth and South Pittsburgh) have been confined within reasonable limits and cut short.

The Secretary has, in his report to the President of the Board, furnished the following admirable summary of the work done during the past year, which demonstrates conclusively the wisdom of the

choice of Governor Pattison in making his appointments on the Board.

"It has established friendly relations and interchange of ideas and results with the National Board of Health, the State Boards of all other States of the Union and of Canada, and the Health Bureaus of many European countries. It has communicated officially with the Boards of Health, Sanitary Committees, and Borough Councils of all cities and boroughs in this State. It has been the means of forming boards of health in places where they did not exist, and of aiding those already formed to systematize and enforce their regulations. It has devised a Model Ordinance on sanitary matters for the guidance of all municipal authorities. It has drawn up a set of Model Rules for Boards of Health, including full instructions for the establishment of special hospitals for emergencies, which may be adopted by any board existing or about to be formed, with such modifications as local circumstances, as charter provisions, or previous legislation may require. It has formulated circulars containing precautions against cholera and smallpox, and regulations for preventing bone-boiling establishments, slaughter-houses, and other offensive industries from becoming sources of danger to the public health; and has distributed these to all city and borough councils, to all superintendents and teachers of public schools, to all jails and charitable institutions, to all newspapers, to all physicians, to all clergymen, to all judges and supervisors, throughout the State, and to upwards of a thousand leading manufacturing firms in the city of Philadelphia. In its distribution to public schools and charitable and reformatory institutions it has obtained the kind co-operation of the Superintendent of Public Education and of the 'State Board of Lunacy and Charities,' which it desires gratefully to acknowledge. It has made inspections of the water-supplies of two cities and one borough at the request of the Councils of the same. It has made inspections of aggravated nuisances existing on the outskirts of three large cities and several boroughs at the request of the Boards of Health or Councils of the same, the nuisances being beyond their own jurisdiction. It has successfully prosecuted and lodged in jail an individual who was poisoning the air of a lovely village for the sake of compelling his neighbors to buy his property. It has divided the State into inspection districts, and appointed inspectors for the same. It has instituted an inspection of the mining regions of the State, with a view to improving their sanitary condition. It has investigated numerous outbreaks of contagious diseases in different parts of the State, personally or through its inspectors, including two of smallpox, both of which, with the prompt and efficient aid of the local authorities, assisted in one instance by the Board of Health of Philadelphia, were successfully nipped in the bud. It has communicated with the officers of railroad and other transportation companies in regard to the transmission of infected passengers or goods, has appointed special inspectors on such lines of travel, and authorized the destruction of several lots of foul clothing found upon their premises. It has caused scientific reports to be made of outbreaks of epidemic disease in the State, particularly that at Plymouth, Luzerne County. It has carefully watched the importation of foreign rags, and insisted on their disinfection before being sorted by the operatives. It has sent delegates to the meetings of the American Public-Health Association, and the Annual Conference of State Boards of Health, and contributed material to their transactions. It has made inspections of the sanitary conditions of six soldiers' orphan schools. It has devised forms for the registration of marriages, and of practitioners of medicine and surgery, and distributed them to all prothonotaries and clerks of Orphans' Courts throughout the State. It has carefully inspected the quarantine system of the Delaware River and Bay, and corresponded upon the subject with the national authorities. It has, by personal interviews and correspondence, consulted with State and county legal officers in order to determine its own exact status and powers. Its committees are now at work upon the following subjects: preparing a compend of the laws of the State on all matters affecting the lives and health of her citizens; preparing a system of organization for rural boards of health; arranging plans for the thorough investigation of all public institutions and schools; and preparing circulars on all contagious diseases. It has prepared for the press, and has ready for distribution, its first annual report.

"Finally, it has held, in the city of Philadelphia, a Sanitary Convention, opened by his Excellency the Governor of the Commonwealth, presided over by the distinguished Provost of the University of Pennsylvania, attended by representatives of State Boards of Health and eminent sanitarians from all parts of the country, before which essays of the deepest interest were read. It has now established an official organ, through whose columns it purposes to give these valuable papers, with other similar information, to the public, and which, under the efficient editorial supervision of the Chairman of its Committee on Preventable Diseases, a gentleman of long journalistic experience, it believes will be a most important instrument in fulfilling the imperative duty imposed upon it by law, '*to*

disseminate information upon these and similar subjects among the people.'"

It will be seen that the record more than justifies the assertion made in the first report of the Secretary, after a brief three months' survey of the field, that "it is evident that the first and most pressing want of the State, from a sanitary point of view, is the organization of boards of health in the rural districts." Indeed, so urgent and so numerous have been the calls upon the Board to perform duties which properly devolve upon local boards in the way of the abatement of purely local nuisances,—duties which it cannot decline, because it constitutes the only legal bulwark between the people and conscienceless or ignorant poisoners of the people's air and food and water,—that other functions which are more distinctively its own, such as registration of vital statistics and the dissemination of information upon sanitary subjects, have been compelled to remain somewhat in abeyance. The development of the former of these two subjects, however, has also been retarded by the want of legislation which shall determine certain of the essential details of execution, and make attention to them obligatory upon the officers to whom they are assigned, while at the same time it assures a proper remuneration for the performance of such duties.

In regard to the latter, the Board has from the first recognized the immense value of the public press as a means of conveying instruction upon these vital topics to the great mass of the population. The utilization of a monthly journal, *The Annals of Hygiene*, as the official organ of the Board, was a step the wisdom of which experience, we trust, will abundantly demonstrate.

PNEUMONIC ENDOCARDITIS.

IN the *Archives de Physiologie*, No. 8, 1886, Netter has gone over the whole question of the relation of endocarditis to pneumonia, and has contributed some valuable facts, which not only confirm the observations of Osler on the frequency of this complication, but also possibly demonstrate the truth of his suggestion that these secondary lesions are dependent upon the micro-organisms of the primary disease.

The figures given by the latter writer were very convincing, for, of two hundred and nine cases of ulcerative endocarditis recorded in the literature, fifty-four were in connection with pneumonia, and in a paper on "The Morbid Anatomy of Pneumonia," read before the Philadelphia Pathological Society, he stated that, of one hundred and five autopsies on this disease at the Montreal General Hospital, endocarditis was present in sixteen cases. Netter has carefully studied three cases which have come under his own observation, reports six other instances occurring in the practice of friends, and has collected seventy-three cases from the clinical records of the past half-century. In seven of his cases the vegetations presented micro-organisms of the same nature as those in the lungs, — viz., lozenge-shaped bodies in pairs and usually surrounded with a capsule. He does not appear to have been very successful in making culture-experiments; but the inoculation of the material from the valves into rabbits, rats, and mice gave very remarkable results. In the first case, a pregnant woman who died on the second day from the chill, there was extensive aortic and mitral endocarditis. Bits of the vegetations, rubbed up in a sterilized fluid and injected into the pleural cavities of rabbits, mice, and rats, produced pneumonia, but no endocarditis. In a second series he lacerated the aortic segments, and on the following day injected the material from the vegetations with the production of endocarditis in the torn valves. In a third series the blood from a patient with pneumonic endocarditis was injected into the pleural cavities

of two mice, and death from pneumonia followed in two days.

Netter finds that the right heart is more frequently involved, in pneumonic endocarditis in one-seventh of the cases, while in ulcerative endocarditis from other causes the tricuspid or pulmonary valves are affected in only one-nineteenth of the cases. He thinks also that in this form the vegetations are smoother and infarcts are less common. Meningitis is a very constant accompaniment of pneumonic endocarditis, occurring in seven-ninths of the cases. Netter holds that it is due to an independent infection and is not embolic, and in favor of this view is the fact that, apart from the presence of valve-lesions, meningitis is not very uncommon in pneumonia.

These experiments of Netter, though suggestive, are not altogether convincing. We still need parallel cultures from the valve-lesions and the hepatized lungs, and more light on the question of the identity of the experimental inflammation of the lung in the rabbit with the primary croupous pneumonia of man.

THE MEDICAL SERVICE OF THE UNITED STATES PENSION BUREAU.

AT the last meeting of the Academy of Medicine, Dr. P. S. Connor, of Cincinnati, read a timely paper upon the medical service of the Pension Bureau. The physician comes professionally in contact with the general government in the medical service of the Army, Navy, Marine Hospital, and Pension service. In the three former there is a rigid examination, and neither chief nor subordinate in the War, Navy, or Treasury Department has anything to do with the selection of the surgeon, and into none of the examinations does political affiliation enter as a factor for appointment. As a result, these are bodies of medical men, capable, learned, honorable, and honored. But the two thousand three hundred Examining Surgeons of the Pension Bureau are the appointees of the Commissioner of Pensions, selected without examination, and often through political influence, and with a tenure of office depending on the pleasure of the Commissioner. A few of the reviewing examiners at Washington have passed a competitive examination, but their tenure of office is uncertain. The office of Examining Surgeon for Pensions belongs, therefore, to the political offices. The duties of the Pension Surgeon are peculiar. He has to determine from present condition whether the alleged injuries or diseases were contracted during the war. Subjective symptoms are generally very largely exaggerated, so that little regard can be paid to them; the objective symptoms may or may not be easily determined, and frequently they are such as will require prolonged investigation and special skill. When the existence of the injury is assured, it must be determined whether it belongs to the army-period or not. After this has been determined, the question must be decided whether or not the amount of present disability unfits for manual labor. Evidently, such service requires experienced physicians of sound judgment, and there remains an immense work to be done by the Examining Surgeon: hence it seems that it would be wise to select carefully the men who compose the Pension Board of Examining Surgeons. But this could not be done while they were appointed as they are now. The essayist thought that it would be well to increase the number of assistant-surgeons in the army and navy, and that then a body of men trained to a knowledge of the manners of soldiers and sailors would be had by whom those applying for pension would be subjected to careful examination. Such examiners could give their whole time to it, and, in addition to the careful safeguards thrown around the Treasury by their skill, they

could also make many examinations as to the present condition of those who were injured twenty years ago, which would make an invaluable contribution to our medical knowledge.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE great excitement at the present time is among the members of the Royal College of Surgeons. There is indeed a very pretty quarrel going on between the members and the Council: the Council have won for the moment, but he would be a wise and far-seeing man who could foretell how the quarrel will eventually end. The members number about seventeen thousand: in fact, nearly every English practitioner who has been educated in England is a member. The Council is elected by the Fellows, a comparatively small body of men, who attain to that dignity either by examination or by selection by the Council: the Council consists almost exclusively of consulting surgeons, and the majority are resident in London. The members claim the franchise,—that is, the right of voting for the election of the Council: until recently the members were entirely ignored, but a few years ago they formed an association and have forced the Council to hold an annual meeting of Fellows and members. At these meetings the members and Fellows talk, and the Council listens, or at any rate maintains silence. When the meeting has dispersed and the talking is over, the Council assembles again and acts. This is what has happened this year at the annual meeting, held on November 4.

In Mr. Timothy Holmes the members found an able and eloquent spokesman. This is no customary figure of speech, for all the surgical world knows of the abilities of Mr. Holmes, and every one who has ever heard him speak knows that he is one of the most clear and incisive speakers in the profession in England: moreover, Mr. Holmes is not only a Fellow, but a former member of Council, and might have been the President if he would: he prefers to stand forward as the champion of the popular cause. He moved a resolution to the effect that it would be well that members of the College of ten years' standing should have the right to vote, and members of twenty years' standing the right to be elected to the Council. Dr. Sanford Thomas, the coroner for Central Middlesex, seconded this not very subversive proposal. The Council said nothing, but Mr. Erichsen, a former President, made a strongly conservative speech, in which he altogether denied the justice of the claims put forward on behalf of the members. The motion made by Mr. Holmes was eventually carried by an overwhelming majority. Later on another resolution, inviting the Council to consider the advisability of admitting the Society of Apothecaries to the Conjoint Board (formed by the Royal Colleges of Physicians and Surgeons for the purpose of granting licenses to practise), was unanimously adopted. It is in connection with this resolution that the quarrel has arisen. The Council, acting within its legal right, has thought it advisable to disregard this recommendation, and within ten days of the meeting formally announced to the Apothecaries' Society its refusal, acting conjointly with the College of Physicians, to admit the Society to the Conjoint Board. It has been supposed that this decision would lead to the extinction of the Society of Apothecaries: it would seem, however, that the wish was father to this thought, for the Society and its legal advisers are quite confident that it will not thus be extinguished, but that the Privy Council will be easily induced to sanction the appointment of Examiners in Surgery, so that a complete examination may be held and a double qualification in medicine and surgery granted. In this case the hope that the act of this year would finally settle the vexed question of a minimum qualification and establish the so-called one-portal system seems to be disappointed.

Gynæcological subjects have recently come in for even more than their usual share of attention. Mr. Knowsley Thornton's paper on three hundred additional cases of complete ovariotomy and twenty cases of exploratory operations was an important statistical contribution: he was able to record a progressive decrease in mortality; each fatal case was described at length; and in speaking of drainage he said that the important point was to remove the tube early enough. The speedy recurrence in cases where solid sarcomata were removed was pointed out, and, in view of the after-mortality from malignant disease of the peritoneum, he strongly condemned a preliminary tapping.

In the discussion which followed the reading of the paper, Mr. Alban Doran supported Mr. Thornton's view, urging that it was not justifiable to tap a cyst supposed to be parovarian, because it was impossible to distinguish between a thin-walled broad-ligament cyst curable by tapping and a thin-walled cyst bearing papillomatous contents: the fluid obtained was similar in both cases, but in the latter disastrous consequences follow the escape of even a minute quantity of the fluid into the peritoneum.

Sir Spencer Wells expressed an opposite opinion: he also stated that since the introduction of antiseptics he had found it necessary to resort to cooling measures in a very much smaller number of cases.

Dr. Playfair thought that the real advance

was the introduction of the system of washing out the peritoneum with water, and stated that he had recently performed five consecutive ovariotomies in King's College Hospital without using antiseptics, and with the most satisfactory results: he added, however, that while he condemned a bigoted adherence to the spray he thought it a useful adjunct in hospital practice, partly on account of the moral effect it produced on the operator and his assistants.

Mr. Thornton hastened to disclaim a bigoted belief in the spray, and explained his use of it on the ground that it kept the hands of the operator, the instruments, and the abdominal walls constantly moist with antiseptic fluid. He thought that the system of freely washing out the peritoneum with water was a great advance: it acted, he thought, by comminuting fragments of material which were either septic at the time of the operation or were in such a condition that in the course of a few hours they would become septic throughout; even if all these particles were not washed away, they would, when reduced to an extremely minute state of subdivision, be more easily and effectively dealt with by the peritoneum itself, which possessed a vital resistance of its own, and was able to destroy injurious particles when these were not so large that they became encapsuled by lymph.

At the Gynæcological Society Dr. Alfred Meadows extolled Sänger's operation as one which ought entirely to replace craniotomy: the latter operation Mr. Lawson Tait, who is President of the Society, called by the short and simple term "child-murder." Dr. Meadows gave some statistics furnished to him by Dr. Harris, of Philadelphia, which showed that thirty-one operations had resulted in saving the life of the mother in twenty-four cases, and of the child in twenty-nine; moreover, the mortality appeared to be decreasing. In the whole series the maternal death-rate was twenty-one per cent., the fœtal seven, whereas in the last twenty cases the maternal death-rate was ten per cent., the fœtal five.

Dr. Barnes objected that the maternal mortality after craniotomy was very low,—less than five per cent.,—and that, in fact, done at the most favorable time and with due skill it did not involve any maternal mortality at all; he excluded cases of extreme pelvic deformity which forbade the hope of extracting the child even after craniotomy.

Mr. Lawson Tait also read a paper at the Medical Society in which he discussed the general principles which should guide the surgeon in deciding whether the operation which he prefers to call "removal of the uterine appendages" should be performed. Following the classification adopted by Sir Spencer Wells in a recent paper, he said the operation was justifiable in (1) certain cases of bleeding myoma, (2) certain malformations of the genital organs and pelvis and accidental obstruction of the vagina, (3) obstinate cases of ovarian dysmenorrhœa or neuralgia in which life or reason was endangered. It was unjustifiable in cases of nervous excitement and madness, and ought never to be done without the consent of a sane patient to whom its consequences had been explained. Reviewing the cases included in these categories, he pointed out that as the patient was, as a rule with few exceptions, sterile owing to the disease for which the operation was performed, the objection that the operation entailed sterility could not be made good.

An important paper on papilloma of the Fallopian tube and the relation of hydroperitoneum to tubal disease was read at the Obstetrical Society on October 6 by Mr. Alban Doran, one of the younger members of the staff of the Samaritan Free Hospital, and well known to pathologists as the coadjutor, with Dr. Goodhart, of Sir James Paget in the preparation of the great catalogue of the Museum of the Royal College of Surgeons. Papilloma of the Fallopian tube, he said, was either a very rare disease or had been frequently overlooked; and during the discussion on this paper (which was adjourned until the meeting of the Society on November 3) Dr. Horrocks stated that at his request careful investigation had been made in the post-mortem room of Guy's Hospital during the last three years to ascertain the frequency of different diseases of the female organs, and that not one instance of papilloma of the tube was discovered. Mr. Doran, in his reply, while admitting the value of this evidence, was naturally led to point to the way in which hydrosalpinx and pyosalpinx had been until recently overlooked by pathologists, while more than one series of specimens had lately been exhibited (by Dr. Kingston Fowler and Mr. Lawson Tait). The symptoms produced by papilloma of the tube do not appear to be very pronounced: a pelvic tumor existed in both the cases recorded by Mr. Doran, but pain does not appear to be an essential symptom, and hemorrhage was absent. The growth is not malignant, and if, as seems probable, it has the same character as other similar growths on the external parts, the disease must be a special form of salpingitis. Dr. Rowth suggested that papillomata in the tube might arise by infection from warts on the external genitals and vagina, and though gonorrhœal infection was stated not to have been, in all probability, ever present in one of the cases, the greatest practical interest attaches to the question whether the affection is inflammatory. Gonorrhœal inflammation nearly always seals up the ostium of the Fallopian tube, and if it did not must excite the most intense peritonitis, whereas a mild catarrh would not necessarily lead to occlusion of the ostium; the catarrhal secretion might thus escape into the peritoneal cavity and cause hydroperitoneum: Dr. Mathews Dun-

can has described that condition as one "in which there is no organic or tangible disease discovered, beyond the conditions of the peritoneum itself, to which the collection of fluid can be referred." That in rare instances this catarrh may be due to papillomatous growths on the tubal mucous membrane was conclusively proved by one of Mr. Doran's cases, for the papillomatous tube was removed seven years ago, the hydroperitoneum never recurred, and the patient has remained free from disease of any kind down to the present time. Both the patients had recently passed the menopause; in the second case, where the disease had caused pelvic pain and difficulty in micturition, the ostium of the tube was closed, and there was no fluid in the peritoneum.

A man bitten by another man suffering with hydrophobia has recently died after undergoing the usual prophylactic treatment at M. Pasteur's laboratory: he returned in good health and spirits, but shortly afterwards became ill and died in five days; the medical attendant considered that the patient died of pneumonia, and this was confirmed after death. Another man recently sent to M. Pasteur, an attendant at the Brown Veterinary Institute, also died soon after his return to this country. Death in this case was due to acute spinal paralysis, attributed to exposure to cold, fatigue, and too much beer. In neither case are the details at present published sufficiently exact to permit us to arrive at an independent opinion.

The suspected connection between embolism and aneurism was a topic of discussion at the Royal Medical and Chirurgical Society on November 23. Messrs. Langton and Anthony Bowlby related an interesting case of multiple aneurism where the connection with multiple embolisms could hardly be doubted; the aneurisms were not formed by dilatation of the arterial walls above the embolus, but by inflammation of the coats at the place where they were in contact with the embolus; in some situations the lodgment of the embolus had led not to dilatation, but to ulceration of the arterial wall; in the latter case an aneurismal sac might eventually be formed by the surrounding tissues. The authors contended that aneurisms occurred only when the emboli were derived from a heart affected by a form of the so-called ulcerative endocarditis. Mr. George Pollock mentioned another case, in a boy, aged 14, who was also the subject of ulcerative endocarditis. Dr. Percy Kidd went largely into the history of the subject, pointing out that the late Dr. Kirkes had been the first to suggest that embolism was sometimes the cause of aneurism, especially in the brain, and that Dr. Goodhart had first started the idea that the character of the embolism was of importance.

By the death of the widow of Sir Erasmus Wilson, the well-known dermatologist, the Royal College of Surgeons becomes possessed of over a quarter of a million sterling. Probably the income derived from this sum will be used for maintaining and extending the museum, and possibly for creating a real pathological institute such as does not now exist in England. Pathology is not in a very forward state in this country, if one may judge from the dreary evenings spent by the Pathological Society. Sir James Paget is, it is said, to be the next President of this Society, and possibly his influence may tend to stimulate the members to move a little out of their common groove: the constant contemplation of large or small tumors in usual or unusual situations quickly palls upon most members, and the audience, therefore, commonly consists of young men. At the last meeting some little sensation was produced by the exhibition of a chondrifying sarcoma removed from the male bladder: but the astonishment, however, caused by its appearance gave way to merriment when Mr. Butlin suggested that the tumor, which was but small, must have got into the wrong bottle!

The General Medical Council has held another session,—the last it will hold as at present constituted. The new members have been elected by the profession during the past week. Dr. Bruce, a general practitioner in Dingwall, is the successful candidate in Scotland; though not yet officially announced, it is known that Dr. Kidd has succeeded in Ireland, and that Mr. Wheelhouse, of Leeds, Sir Walter Foster, of Birmingham, and Dr. Glover, of London, have beaten their eleven opponents in England. These three gentlemen were those selected by what has been known as the "Birmingham Committee," which undertook to choose three candidates when the British Medical Association at Brighton failed to arrive at any conclusion. The members are reported to be: Wheelhouse, 8548; Foster, 7718; Glover, 6614. Dr. Glover is a general practitioner in the North of London, who has long been connected with the *Lancet;* Mr. Wheelhouse was formerly a general practitioner, and is now a consulting surgeon, in Leeds; while Sir Walter Foster is a physician in Birmingham and lecturer on medicine in the medical school there.

The committee appointed by the Pharmaceutical Conference at its last meeting appears to be appalled by the magnitude of the task it has undertaken: its commission is to make investigation as to (1) formulæ for flavoring preparations (elixirs); (2) the best form and the best preparations of new drugs; (3) the composition of mixtures sold by advertising wholesale chemists under a variety of fancy names. The committee would publish formulæ for rival mixtures which could be prepared by all manufacturing chemists, and might thus supplant the advertised mixtures.

The General Medical Council also has ap-

pointed a "reporter" to make preliminary abstracts of new works in pharmacy and to test their accuracy: the reports are to be used by the Pharmacopœia Committee in keeping the British Pharmacopœia up to date.

DAWSON WILLIAMS.

ST. LOUIS.

RECENTLY the following interesting case of supposed primary carcinoma of bone occurred in the practice of Dr. H. H. Mudd, of the St. Louis Medical College.

The patient, a man 69 years of age, had complained for four months of pain in the right leg, which was supposed to be rheumatic until about last July, when a little ulcer appeared in the skin over the head of the tibia, through which a sanious discharge issued: he took to his bed about a month later, and was and had been under the care of the family physician until the consultation with Dr. Mudd was held.

When Dr. Mudd first saw the case, ten days before operating, the popliteal space was filled with pus, the head of the tibia was perforated and the site of what seemed to be the result of an osteitis. A drainage-tube was passed through the tibia and across the popliteal space, bringing it out posteriorly. A few days later another accumulation of pus below and to the inside was drained.

There was little or no tumefaction of the bone. Amputation was advised and performed. There was evidence of destruction or rapid breaking-down of the bone. After the bone had been cut through, the medulla was seen filled with a mass somewhat different in appearance from marrow, and the medullary cavity enlarged at the expense of the bone, and the bone was much thinner about the tumor. The neoplasm examined microscopically proved to be a carcinoma.

No evidence of a primary tumor was found anywhere. The patient died twelve days after the operation: he was well advanced in life, and in poor condition at the time of the operation. The stump had healed, however, before the patient died. A post-mortem was not obtained.

Rapid disintegration and suppuration, without any evidence of a tumor (except the fluctuating tumor in the popliteal space, which proved to be an accumulation of pus), were marked features of the case.

Dr. C. E. Michel recently performed a double cataract operation before his class at the Missouri Medical College, using the "modified method." The patient lived at a distance, was poor, and both cataracts were ripe, and, to save her time, expense, and trouble, she and the doctor arranged to have both eyes operated on at the same time.

At the time of the operation the iris protruded and was returned. After the operation the lids were lightly closed, leaving a slight opening between them (not closing them to exclude the light), and a plaster of gold-beaters' skin applied one and a half inches long by half an inch wide to "fix" the lid; patient put to bed and kept quiet. In his cataract cases Dr. Michel does not bandage the eye and place the patient in a dark room, as is the usual practice, but treats the case in the open light, and lays but slight restraint on the movements and actions of the patient. The patient in the case under consideration was up and about on the fifth day after the operation; walked two blocks and appeared before the class on the eighth day, at which time the hernia of both irides was remedied by performing double iridectomy. Three days later she was up and about; she never complained of the light: she could "feel" it, but it gave her no pain.

This "open method" of treatment has been used by Dr. Michel for a period of twenty years, and always with good results. He claims to be able to have evidence of any threatening mischief by inspection, and thus be able to combat it earlier than by the method in vogue, where it is necessary to wait until the patient complains of pain before it is known that trouble is brewing, and then the bandages are removed and strong light allowed suddenly to enter the eye for purposes of examination, thereby increasing the existing inflammation.

He says the retina in cataract is not inflamed, so why should light be excluded? It does endanger inflammation from irritation later on, when the eye is exposed to light after having been bandaged. The bandage, instead of keeping the corneal wound in apposition, would tend to do the opposite, as pressure is made on the lid, and through it on the eyeball, by means of the compress. He thinks nature has made the best provision for the adaptation of the edges of corneal wounds by compression in the lid, which closely fits the eyeball: and if it be drawn down to cover the wound, and "fixed" with a piece of plaster, it is the best of all fixed dressings.

In a second case, operated on before his class at the St. Louis Poliklinik or Post-Graduate School of Medicine, the patient, a woman, was 65 years old. Graefe's method was used: the after-treatment was as above (the "open-light" method). On the fifth day after the operation she was up and about; on the eighth day the plaster was removed, and the patient was going about as usual.

He treats iritis in the open light, uses no shade or coverings, and patients go and come without protection.

This would lead me to speak of the Poliklinik, where the last cataract and the iritis were seen. It is about eighteen or twenty months old, and now has clinics which compare favorably with clinics anywhere. The Laryngological, Dr. W. C. Glasgow director, is very large, and reminds one of some in

Vienna; the Gynæcological is under the charge of Dr. G. J. Engleman; General Medical, B. G. Robinson; and the Genito-Urinary and Surgical, Dr. H. Tuhalske; the Ophthalmic department has been referred to already, and the Dermatological is one of the best. The *chef* of this department, Dr. W. A. Hardaway, is well known in the East and abroad as a clinical observer and writer.

A short time ago in his clinic a case of dermatitis exfoliativa infantum (V. Rittershain's disease) occurred which was typical in the extreme. It is the third case that has occurred in Dr. Hardaway's practice. The child, a female 6 weeks old, was observed, very soon after birth, to have red spots on hands and feet looking like a burn. When brought to the clinic the disease occupied the greater part of the body,—viz., arms, legs, face, chest, and some small areas on the abdomen and back. The epidermis exfoliated in large lamellæ, leaving the skin shining and of a violaceous hue; the buccal mucous membrane was slightly involved, and the anterior nares were occluded with crusts. In general, there was no moisture, but the folds of the skin about the elbow and shoulder and knee were cracked and fissured, and here a little moisture was noticeable, as also about the mouth and possibly about the ear; no constitutional disturbance; mother and father both healthy people, and other healthy children in the family.

The treatment consisted in free inunctions with vaseline. Patient remained away from clinic a few days and came back again, to remain away then for good. It was learned at the clinic that the patient died about a week after the date that it was to return to the clinic.

St. Louis now has four medical schools. The aggregate number of students is about as usual, though the attendance at the individual schools is somewhat less than it was last year, owing to the establishment of a new (fourth) school,—the Beaumont Hospital Medical College,—which has about sixty students. It was organized last spring, and is giving its first course. It contains some men of considerable merit, having a corps of nineteen professors and one demonstrator. It requires but two years' study prior to graduation. The Missouri Medical College has about two hundred students. It is now known as the Medical Department of the State University of Missouri, students being privileged to attend their first course or courses at the State University at Columbia, and their last at the Missouri Medical College in St. Louis. Two years obligatory; three years advised. This school has made a step in the right direction by establishing a biological laboratory, and by giving a systematic course on the use of the microscope, the director of this department being Dr. L. Bremer.

The St. Louis Medical College, of which Dr. Hodgen was for years dean, has recently made a number of changes in its faculty. Dr. Elsworth F. Smith, Professor of Clinical Medicine (and, before there was a separate chair for it, also of Pathology), resigned last spring, and is now Emeritus Professor of that chair; Dr. W. E. Fischel was made Clinical Professor of Medicine; Dr. L. Charles Boislinière, Professor of Obstetrics and Gynæcology, resigned, being now Emeritus Professor of Obstetrics, Dr. Scott taking the chair of Obstetrics, and Dr. Barret, who for a long time had been Lecturer on Gynæcology, was appointed to the new chair of this title. Dr. Barret died in August last, and his chair is now temporarily filled by Dr. Schwarz. Dr. B. J. Primm is the new Professor of Anatomy, Dr. Mudd, the retiring professor, reserving Surgical Anatomy as a connecting link to the chair of Clinical Surgery, which he has held since Dr. Hodgen's death.

The different medical societies are well attended, and usually have interesting meetings. The St. Louis Medical Society is the largest in point of numbers. It meets weekly in the Polytechnic Building; it has a good library and a large number of periodicals. The Medico-Chirurgical follows in point of numbers, having semi-monthly meetings in the large hall of the Poliklinik. One of its features is the reading of volunteer papers at regular intervals by members, who also have a nice library, where may be seen files of almost all the medical journals printed.

A small but excellent society is the "Verein der Deutschen Aerzte," which has a membership of about twenty-four, and an average attendance of eighteen. Each member is obliged in his turn to read a paper or demonstrate something. It is strictly a working society.

The profession is improving rapidly here; men are working hard; more students are taking long terms of study, and many indulge in finishing touches; for that purpose the Post-Graduate School was started. The profession is improving in appearance and in social standing too. Years ago, a physician riding in a carriage or coupé was looked on with a little disfavor; now, however, the gentlemen with good practices all have carriages or coupés; it has gotten to be "the thing." In St. Louis, as in New York and Philadelphia, the better class of physicians have their offices at their homes, or, at any rate, in the immediate vicinity; in fact, all strive to have them at their homes. Some of the offices are beautiful in appearance and splendid in their appointments. The surgeons who formerly had "students" as assistants now have first-class men as such, rapid advances in education having demanded experienced and well-schooled assistants. Many of the larger general practitioners are acting similarly.

Persons practising medicine in this State are required to register. The State Board of

Health requires a diploma from a reputable medical school or "five years or more of the practice of medicine prior to 1883," the year the law was passed. The City Board of Health requires registration, the desideratum being a certificate from the State Board.

The Anatomical Association, consisting of the teachers of anatomy of the various chartered medical colleges in Missouri, is engaged in the attempt to get a new Anatomy Act passed, since the existing statute for regulating dissection is practically almost prohibitory. The proposed act is essentially similar to the acts of Pennsylvania and Illinois, which are said to work satisfactorily.

November 19, 1886. W. S. B.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA NEUROLOGICAL SOCIETY.

A STATED meeting was held October 25, 1886, the Vice-President, CHARLES K. MILLS, M.D., in the chair.

Dr. MORRIS J. LEWIS read a paper on

A PARTIAL STUDY OF THE SEASONAL RELATIONS OF CHOREA AND RHEUMATISM.

Dr. WHARTON SINKLER said that this paper was valuable and interesting, because it showed the close relation between chorea and rheumatism, which has been denied by some authors. For instance, Sturgis had two hundred and nineteen cases of chorea in the Hospital for Sick Children in London, of which number twenty per cent. also had rheumatism; but he did not attach much importance to this connection, because, as he stated, fifteen per cent. of all children have rheumatism. Other writers have expressed the same views. This paper also seemed to prove the relationship between the storm-centres and the occurrence of attacks of rheumatism and chorea.

Dr. G. E. DE SCHWEINITZ reported

EIGHT CASES OF TOBACCO-AMBLYOPIA, ONE COMPLICATED WITH DISEASE OF THE SPINAL CORD.

Since 1854, when Mackenzie showed that defective vision might be produced by tobacco-smoking, and since ten years later, when the subject was renewed and enlarged by the observations of Hutchinson, tobacco-amblyopia has become one of the well-recognized facts of ophthalmological science. As is well known, progressive and usually equal failure of vision, unimproved by optical therapeutics; a feeling of wretchedness on the part of the patient; an ill-defined ophthalmoscopic picture; and a symmetrical oval scotoma in the fields of vision, lying between the fixing point and the blind spot, and often including both, in which the perception of green and red is especially defective, constitute the marked symptoms of this affection.

[Notes of the eight cases are omitted.]

In three of the cases reported the ophthalmoscopic examination revealed "hazy disks," either with or without full dark retinal veins (Cases I., II., and III.); in two, if the last record be included in the list, there were no fundus changes (Cases VII. and VIII.). In one the optic nerve was pallid, the arteries rather small,—perhaps the appearance of beginning atrophy (Case IV.); and in one the nerve showed evidences of gray atrophy (Case V.), while in another the appearances were those of a subsiding neuritis (Case VI.). Three of these cases are perfectly typical instances of tobacco-amblyopia (Cases I., II., and III.); and two of them, if not characteristic cases, at least showed the result of tobacco-impression (Cases VII. and VIII.). Case IV. is an atypical one, inasmuch as the scotoma surrounded the fixation, but did not include it or pass to either side, and, furthermore, is noteworthy because of the fact that the tobacco found its entrance into the system by absorption through the skin: this woman worked in tobacco, but did not use it. Case V. may be one of those rare instances in which a central scotoma appears with a spinal atrophy of the optic nerve; but, inasmuch as the man used tobacco, although moderately, its influence cannot be excluded. An almost precisely similar case is recorded by Gowers ("Medical Ophthalmoscopy," p. 111). In Case VI. it is doubtful if the use of tobacco produced the scotoma, although, as in the last instance, the patient was accustomed to its use, and hence its influence cannot be excluded. The whole subject of tobacco-amblyopia has so often and so thoroughly been discussed, notably by Mr. Nettleship ("St. Thomas's Hospital Reports," 1878), that it is useless to do more than report these cases and point out the features that are interesting.

Dr. B. ALEX. RANDALL remarked that some ophthalmologists disbelieve in the existence of tobacco-amblyopia. Very few cases have been put on record in which the influence of alcohol could be wholly excluded; but the combination of alcohol and tobacco is certainly a serious disturbing element in a number of cases. This affection is constantly coming under notice,—occurring some eight or ten times in a thousand cases. While the scotoma is usually of an oval form, he had seen it distinctly annular (as in Case IV.) in a case typical in other respects.

It has recently been claimed that the absolute quantity of nicotine used does not bear that relation to amblyopia that we should infer, and that those who smoke the finest cigars are more liable to this affection than those who smoke the poorest and strongest.

Dr. JAMES HENDRIE LLOYD asked if this

affection were due to neuritis or to some disturbance of the intraocular circulation. The cases reported suggested an interesting analogy between tobacco-amblyopia and peripheral neuritis, especially that form due to toxic agents. Is this a form of toxic neuritis of a special nerve?

Dr. J. MADISON TAYLOR, referring to one of the cases reported, asked if it were not possible to have a powerful effect from the absorption of tobacco by the skin and lungs. In children working or living in tobacco-shops he had in several instances seen profound disturbance of the heart as the result of absorption.

Dr. LOUIS J. LAUTENBACH remarked that there had always been an element of doubt about these cases, and that of late this had become stronger. There are cases reported in which alcohol has been stopped while the tobacco has been continued, and the patients have gotten well. Dr. Minor, of Memphis, reports eight such cases. In addition to the discontinuance of alcohol, he administered in these cases either iodide of potassium or strychnia. Nettleship, Foerster, and a few others have succeeded in curing some of these amblyopia cases by the discontinuance of tobacco alone. About two years ago, at the Philadelphia Eye and Ear Dispensary, he had experimented in this matter, and had cured a number of cases by removing alcohol, allowing them to use tobacco, without the use of any medicines. The same treatment had resulted satisfactorily in two cases treated in private practice. One case was that of a professional base-ball player, who was in the habit of drinking thirty-five or more glasses of whiskey and smoking from eighteen to twenty-five cigars a day. When examined, both eyes gave $V = \frac{3}{LX}$? The patient was directed to stop the use of strong liquors, but to keep on with his tobacco. In four days later $V = \frac{3}{XXXV}$. Vision continued to improve, although no medicines were used.

The condition which causes this amblyopia may be a slight grade of retro-ocular neuritis, involving only the macula lutea fibres, which may be induced not only by tobacco, but also by alcohol; lead occasioning it in some few cases. Depressed conditions of the system may probably cause it. This amblyopia with central scotoma is coming to be looked upon not as a special symptom of tobacco-abuse, but rather as an indication of the depression of the general system which may be brought about by various poisons.

Dr. WHARTON SINKLER referred to a paper published in one of the New York journals by Drs. Roosa and Ely, giving the results of the examination of a large number of workers in cigar-factories, many of those examined smoking a great deal. Only a very small proportion of these cases was found to present any defect of vision or any disorder of the nerve. He asked if, in the experience of other members, they had found that a large proportion of nervous diseases were attributed to tobacco. He saw but few patients at his clinic at the Infirmary for Nervous Diseases with nervous disorders which could be directly attributed to the use of tobacco.

A point to be remembered in the consideration of this subject is that a person who takes alcohol will use more tobacco than one who does not. If he stops his alcohol, he will take less tobacco.

Dr. MORRIS J. LEWIS stated that in studying the subject of writer's cramp he had found that in the majority of cases the use of tobacco increased the difficulty. A few out of forty-three cases said that it did no harm, and three said that it was of service.

Dr. FRANCIS X. DERCUM asked if those who used tea or coffee to excess, especially tea-tasters, presented symptoms analogous to those presumably caused by tobacco and alcohol.

Dr. B. ALEX. RANDALL said that there were some cases in which alcohol *could* be entirely excluded in the causation of this affection. As to the pathology of the trouble, it is interesting to note that he knew of no case on record of true neuritis in the sense of anything like a choked disk which had any apparent relation to tobacco-abuse, although such cases are not rare in lead-poisoning and other toxæmic conditions. In all cases of actual neuritis of the optic nerve, as in inflammation of other nerves, strychnia has to be carefully avoided in the acute stage. In most cases reported the use of strychnia had no injurious effect, and, in fact, caused or was followed by improvement. In some cases where strychnia has been given and the alcohol and tobacco both continued, recovery has taken place. The amount of poison required to produce a certain effect probably depends upon the constitution and condition of the patient. If the general condition is brought up, a given amount of the poison no longer has the same effect.

Dr. CHARLES K. MILLS, referring to the question of Dr. Sinkler, stated that his experience agreed with that of Dr. Sinkler, that nervous disorders are rarely attributable to the use of tobacco, although some cases of tremor and general nervousness and a few other affections undoubtedly originate in this way.

Dr. GEORGE E. DE SCHWEINITZ, in closing the discussion, said that he believed that in these cases there was an axial neuritis. He had no experience with the poisonous effects of tea and coffee. Some of the cases reported had recovered although the free use of spirits was continued. One of the patients continues to drink a pint of whiskey a day, and yet his vision has remained normal since the discontinuance of tobacco. The only way to reach a satisfactory explanation of this subject is to continue the experiments.

One object in presenting this series of cases was to call attention to the importance of a careful study of the field in nervous cases. If this were done more frequently, many interesting discoveries would probably be made.

Referring to the question of Dr. Taylor, he said that tobacco is freely absorbed through the skin, but inasmuch as it is rare to find scotomata under such circumstances he had reported the case.

Dr. FRANCIS DERCUM reported

A CASE OF UNUSUAL PARESIS OF THE FOREARMS.

Dr. CHARLES K. MILLS referred to three cases which had been reported a few years ago by Dr. Kerlin and himself. These cases were studied at the School for Feeble-Minded Children at Elwyn. The patients were brothers, and in them was a marked combination of pseudo-hypertrophy and muscular atrophy. One of the boys, who has since died, presented in the calves the typical appearance of pseudo-hypertrophy and also in one or two other isolated portions of the body. In the back, however, were all the distinctive signs of progressive muscular atrophy. In the second case the changes were principally those of progressive muscular atrophy. In the third there was a combination of the two conditions. Why in one case we get the pseudo-hypertrophic form, and in another the atrophic form, he was not prepared to say. He believed that in all cases there are cord- and nerve-lesions, but he did not know which of these was primary. In the treatment of such cases, that pursued in the present instance would seem to offer the most hope. He was in the habit of putting these cases on strychnia, iron, cod-liver oil, and similar tonic and nutrient remedies. He had never seen much benefit from local treatment, but if myositis was present he thought it worthy of a trial.

Dr. JAMES HENDRIE LLOYD said, with reference to the age at which this affection may develop, that he had recently seen a case in which a married woman, 30 years of age, who had been under treatment on several occasions without a positive diagnosis having been made, returned after an interval of four months with hypertrophy of the calf, lordosis, and other characteristics of pseudo-muscular hypertrophy. This was the first case which he had seen in which the disease had apparently occurred as a primary disease in an adult with no hereditary tendency.

Dr. WILLIAM OSLER remarked that some observations had been made by an English physician with reference to the atrophy which follows great use of the muscles. After examining the microscopic specimens, he agreed with Dr. Dercum in regard to the condition present in this case. There was no essential difference between the atrophic and the pseudo-hypertrophic form of the disease, and both may be present in the same case.

Dr. WILLIAM OSLER exhibited the following specimens:

PACHYMENINGITIS.

J. K. was admitted to the Drunkards' Ward of the Philadelphia Hospital on August 26, with delirium tremens, and died September 4. I did not see him during life, but from the account given by the resident physician he appears to have had an ordinary attack of delirium tremens without any paralysis, local or general. He was not in a condition to give a satisfactory account of himself. Death took place from exhaustion. The post-mortem showed an extensive pachymeningitis of the right half of the dura mater. The specimen presents layers of exudation two lines in thickness over the central portion of the dura, gradually becoming thinner towards the tentorium or the orbital surface. In these regions there was a delicate uniform sheeting on the dura mater and no hemorrhage had as yet taken place, but on examination with a low-power lens there could readily be seen a plexus of wide vessels. In the central part there were several layers of altered blood, alternating with colorless firmer exudation. The surface of the pia mater of this hemisphere was a little stained, but there had evidently not been any pressure upon the convolutions. There were no other lesions.

PHTHISIS—TUBERCULAR MENINGITIS—APHASIA.

J. McD., æt. 36, laborer, was admitted to the Philadelphia Hospital June 5, with phthisis. There was nothing special in his family history; five of his brothers and sisters had died from causes unknown to him. He had been ill for over eighteen months with cough, fever, chills, and sweats,—had brought up blood, and had had severe diarrhœa. When I saw him first, on September 4, there were signs of extensive disease in both lungs. Ten days before, he had two convulsions, after which he had some difficulty in talking. On the 4th he looked bright and intelligent: the pupils were dilated, and there was no paralysis. Expressed himself with difficulty. When asked his name, said *Joseph Mac*, but could not say the *Donald*. After several attempts, and a good deal of worry, he did so, and seemed much pleased. Some words he said clearly, others he could not. Thus, he could read the letters of the word *shaken*, but could not pronounce it. He was delirious at times during the next two weeks, and one night he got from the ward on the fire-escape. The aphasic condition improved somewhat. The eye-grounds were examined twice, with negative results. At the time of my visit on September 10 he had an epileptic seizure, strong spasm of respiratory muscles, and great lividity. Tonic spasms of arms gradually relaxing and becoming choreic. Facial muscles in violent action: face drawn

to the left, eyes to the right (strongly) and upward. He became unconscious the next day, and died on the 14th. The autopsy showed extensive disease of the lungs. The brain was large; at the base the membrane was thickened and infiltrated, and tubercles existed along the vessels. On exposing the Sylvian fissures, the pia on the left side covering the insula was very thick and studded with tubercles the size of a pin's head. The process was most advanced upon the three or four posterior gyri of the insula; the gray matter was reddened and soft; the third left frontal convolution was not specially involved; there were a few isolated tubercles on the pia, but the membrane was not thickened. In the right Sylvian fissure there were tubercles scattered along the vessels, and the arteries of the anterior perforated spaces presented many bead-like and oval swellings. The ventricles were dilated and their walls softened.

EMBOLISM OF RIGHT MIDDLE CEREBRAL ARTERY—CHRONIC NEPHRITIS.

J. W., laborer, aged 49, was admitted to the Philadelphia Hospital October 7, 1886. No special history could be obtained, as he was very dull and heavy. When I saw him on the 9th he was apathetic; answered questions with difficulty. The face was anæmic, and he had a decidedly renal look; the pulse was slow and hard, 60 to the minute; no increased heart-dulness, possibly a murmur at apex, but it was not at all distinct, and at base was very ringing. There were albumen and casts,—hyaline. The case was regarded as one of chronic interstitial nephritis.

On the morning of the 12th he had a hemiplegic attack. I found him at one o'clock P.M. comatose, with puffing respiration and complete left hemiplegia, including face; right pupil larger than the left. He died during the night.

The autopsy showed cirrhotic kidneys, slight atheroma in large vessels, moderate hypertrophy of left ventricle. The mitral valve presented recent vegetations, three in number, on the auricular face of segments, freely movable, and on the posterior flap a flattened area looking as if eroded. The right hemisphere of the brain looked fuller than the left, and the vessels were not so full, particularly in the central region; the vessels of the circle of Willis were denuded *in situ*, and the right middle cerebral just beyond the first two branches (temporal) was found plugged with the firm embolism here shown. It was very evident before opening the vessel, as it showed grayish-white throughout the coat, while on each side of it were dark clots, and the branches beyond it were very small. The embolus was firmly adherent, and had a small pale clot on its proximal and a firm dark one on its distal side. Examination showed it to be an endocardial vegetation, and it doubtless came from the rough spot on the posterior segment. The convolutions of the central portions of the hemisphere were swollen and œdematous, particularly the gray matter, and soft. There was a light gray-yellow tint, but there had not been time for much change. The right anterior cerebral was greatly enlarged, three times as big as the left, doubtless a compensatory process.

Dr. CHARLES K. MILLS remarked that cases of pachymeningitis hæmorrhagica were somewhat common in the Philadelphia Hospital. He had met with a comparatively large number of cases in making autopsies in that institution. A form of hemiplegia met with in the wards of this hospital is undoubtedly due to pachymeningitis hæmorrhagica. These cases make partial recoveries, and then again break down, and at the autopsy is found the condition exhibited to-night. He had reported one case five years ago, with a number of other cases, in the English journal *Brain*. This condition is sometimes mistaken for embolism, hemorrhage, or some other form of disease producing hemiplegia.

In some of the cases he had seen there had been distinct naked-eye flattening of the convolutions of the motor region, which he supposed accounted for this peculiar, variable form of hemiplegia.

Adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

THURSDAY, NOVEMBER 4, 1886.

The President, B. F. BAER, M.D., in the chair.

DR. JOSEPH PRICE exhibited specimens from two cases of

PYOSALPINX.

Dr. M. PRICE exhibited specimens from one case. All of these were of gonorrhœal origin. Those by Dr. J. Price were removed from prostitutes. That exhibited by Dr. M. Price was from a married woman who had been infected by her husband. The tubal disease manifested itself soon after childbirth. The menstrual period had always been very painful, and had kept her in bed from eight to ten days.

Dr. HOWARD A. KELLY exhibited a

SARCOMA

as large as a man's head, which he had removed from the anterior abdominal wall. It had its origin at the transverse tendinous band of the right rectus muscle, just below the umbilicus. The mass was about eight inches by ten, and hung pendulous under the greatly thickened skin of the right umbilical, inguinal, and iliac regions. The great point of difficulty was in determining before operation whether the mass did not spring from a

small hernia slipped through the umbilical ring, which was greatly drawn out on one side over the tumor, and deep in which the fibre-like cords of attachment could be felt. The tumor was very vascular, but was readily removed, and the patient made a perfect non-febrile recovery.

Dr. KELLY also exhibited a specimen upon which he desired a report by the Microscopical Committee. The case was one of great interest,

AN OVARIAN PREGNANCY,

upon which Dr. Kelly had operated within the past twelve hours.

The patient, a German woman who had had one child by forceps delivery two years ago in Germany, had since been regular in her menstruation until October, when she went two weeks over time, and was then roused in the night by sudden violent pain in the right leg and groin, extending obliquely down the right ovarian region. With the pain came a profuse uterine flow, which lasted for two weeks, with intermissions. From excellent health she was immediately prostrated and became miserable, with elevated temperature and quick pulse. She had no organic disease, but a small tumor at the extremity of the right Fallopian tube. The tumor was about two and a half or three inches in diameter, softish, not sensitive, freely movable in the pelvis. In front of this a sharply-defined round ligament could be traced out to the brim of the pelvis, and above this the flatter cord of the Fallopian tube could be felt. The ureters were enlarged, as Sänger has noticed and as the speaker has frequently verified in pregnancy. The uterus was of a size approaching two months' pregnancy, and the cervix was remarkably soft for the early stage of pregnancy.

Dr. Kelly sent invitations to Drs. R. P. Harris, J. G. Allen, Freeman, John and Frank Haynes, Joseph Hoffman, George Horn, and William Ferguson to be present at an abdominal section for extra-uterine pregnancy, and in their presence the operation was carried out. (The patient up to date of publication has made uninterrupted progress towards recovery.) Dr. Kelly also exhibited a chorionic membrane from a uterus, with a four weeks' fœtus attached.

Dr. BEATES remarked that the lining membrane of the cyst was easily separated from the wall, and he thought the specimen was most probably a parovarian cyst.

Dr. JOSEPH PRICE thought the cyst could be entirely shelled out. He considered that it had none of the characteristics of a tubal pregnancy.

Dr. KELLY, in closing the discussion, demonstrated in the extra-uterine and in the uterine specimens an identical membrane which could be detached, and which was the amnion. He demonstrated ovarian tissue completely surrounding the cyst, thus proving that it was not parovarian in its origin. The lining membrane underlying the apparent amniotic membrane is a soft tissue never seen in an ovarian cyst. The specimen was referred to a committee.

Dr. LONGAKER exhibited a fibro-myomatous substance which had been expelled from a uterus twenty-three days after normal labor. The placenta came away entire; there was a post-partum hemorrhage on the second day. In the third week a rise of temperature occurred. The temperature became normal after the expulsion of this mass.

Dr. KELLY said that, judged by the macroscopic appearance of the specimen alone, and with great certainty in view of the history, this flat elongate mass with one semicircular rounded edge, and with long shreds hanging to it, was a portion of a retained placenta. A question is by this brought up upon which it is of the utmost importance that every member of this Society should have positive convictions, in order that our practice should be uniform, and that is, What shall be done in the case of a puerperal woman who has an elevated temperature and a foul-smelling discharge from the vagina? When other manifest cause was absent, he thought that every such patient should be placed in a convenient posture and the uterus thoroughly scraped with a dull curette, to be followed by a swabbing with an antiseptic. Thousands of women to-day suffer from neglect of this simple precaution of removing stinking shreds of decidua and pieces of placenta, which, remaining, cause subinvolution, chronic endometritis, and cellulitis lingering for years, or even a more acute and rapidly fatal septic process. Dr. Kelly prefers the lateral semiprone position for convenience of exposure and manipulation, considering the objections which have been urged against this as purely theoretical.

Dr. BAER would prefer the patient on her back for scraping or washing out the uterus after labor, using tincture of iodine or bichloride solution.

Dr. BEATES has made it a rule, whenever the temperature rises after labor, to introduce the finger or curette into the uterus and remove any adherent masses.

Dr. LONGAKER, in closing the discussion, said that he had not the slightest doubt that the specimen had been a fibroid tumor buried in the tissues of the lower portion of the uterus: the contraction and involution of the uterus cut off its supply of blood and partially enucleated it. Time was required for this process. The rise of temperature did not excite immediate suspicion, as the case was a hospital one and the wards were crowded at the time.

Dr. BEATES, on behalf of the committee, stated that the microscopic examination of the "ovarian fibroid" presented by Dr. Baer

at the October meeting showed it to be a neoplasm developed from the epithelium of the ovary: it was a true scirrhus, with nothing ovarian about it except its origin.

HYSTERORRHAPHY.

Dr. HOWARD A. KELLY read a paper, written for the Society in the spring of this year, upon a new operation, which he called hysterorrhaphy, or the *suspension by suture* of a *viciously-posed uterus*,—that is, an organ prolapsed or retroflexed which it is impossible to relieve by any line of treatment applied per vaginam.

The speaker first applied this method April 25, 1885, upon a patient who had been under the care of several other specialists and under his own care for nearly three years. The uterus had lain acutely retroflexed, with a large soggy fundus in Douglas's pouch, below the level of the cervix. Months of rest in bed, combined with careful packs and counter-irritation, and for a long time applications to the endometrium, failed to cure the flexion even temporarily.

The patient had been operated upon a year previously, removing a very tender ovary per vaginam. On this occasion the left tube and ovary were removed, and, as the right tube could not be felt, he concluded that it had atrophied. The uterus was then raised and a sharp band of cicatrix-like tissue felt half encircling it in the angle of flexion, when the futility of any attempt to relieve the condition from the outside was at once evident. Silk sutures were passed through the left horn of the uterus, and the body suspended from the anterior abdominal wall, about one and a half inches above the pubis, to the left of the incision. The suspensory sutures were passed between two ligatures encircling the horn and the base of the pedicle, to avoid the dangers of tearing out and of bleeding.

The uterus, thus suspended, remained in place one year, when the right tube enlarged to a hydrosalpinx, and just before operation for its removal dragged the fundus over.

Dr. Kelly urged that in future both cornua be utilized and attached between one and a half and two inches above the pubes, to allow room for free expansion of the bladder; and, again, that while in most instances the disease is of such long standing as to involve chronic incurable disease of the appendages and to necessitate their removal, yet in some cases the good effects of drainage of the latter, which are raised with the body, should be tried. The operation is to be urged where the long-retroflexed, infiltrated uterus is unable to stand up straight alone after removing diseased ovaries and tubes; and if adhesions bind the fundus down, they should be carefully severed.

He also insisted that the operation for shortening the round ligaments was not admissible for retroflexion alone, as, owing to enormous mechanical disadvantage, the slightest degree of relaxation would allow a reproduction of the deformity.

While in simple prolapsus, if a suprapubic operation of any sort were ever necessary, which the speaker doubted, he would prefer a simple, aseptically-made, abdominal incision and direct support by attaching the fundus to the anterior abdominal wall, to an operation which has a doubtful and possibly a high rate of mortality, and of which the ratio of success is even more problematical.

The operation has been devised and performed independently by a number of prominent gynæcologists in various parts of the world, among whom are Koeberlé, Bardenheur of Cologne, Hennig of Leipsic, Czerny of Heidelberg, a surgeon in the north of Italy, and Lawson Tait; probably Keith, and two cases, not published, which Dr. Sänger of Leipsic kindly gave the writer during the past summer.

Dr. DRYSDALE remarked that he had performed a second operation upon a lady upon whom, eighteen years previously, Dr. Atlee had performed ovariotomy for the removal of an ovarian tumor. At the first operation the uterus was found prolapsed. In this operation Dr. Atlee had used the clamp to secure the pedicle, and at the second operation the uterus was found attached to the original wound. The prolapse had been effectually cured. He thinks both cornua should be secured to the abdominal wall. He had never met with a case of retroversion that could not be relieved by pessary after curing the accompanying endometritis. Many years ago, a lady who had been for eight years under the care of Dr. H. L. Hodge for retroversion, and in whom the presence of a pessary excited such expulsive efforts that it could only be worn a week at a time, came under the care of Dr. Drysdale. He treated the endometritis first, and, when it was cured, a pessary could be retained, and complete relief was secured.

Dr. JOSEPH PRICE remarked that Tait considers it dangerous to stitch the fundus uteri to the abdominal wound, and has abandoned it. In some operations he introduces sutures to draw the uterus high up, that he may more readily remove the tube close to the cornua.

Dr. BAER thought it seemed the most natural method to stitch the fundus to the abdominal wound. He asked why Dr. Tait had considered it to be dangerous. He thought the field of Dr. Kelly's operation would be small, as, when the endometritis was cured, a pessary or other support would relieve the retroversion or flexion. After laparotomy or removal of the uterine appendages, it might be advisable in some cases to draw the uterus up. He had had no experience with such a procedure. He did not like the Alexander operation; he considered it unscientific, and

in many cases it has failed to cure the displacement.

Dr. LONGAKER feared that, granting that anteversion could be secured by Dr. Kelly's method, the bladder would not be allowed to expand; a fixed anteversion would itself be pathological. He would hesitate to stitch the fundus to the abdominal wall, even after removal of the appendages. Retroflexion does not necessarily produce discomfort, as some cases have no symptoms to call attention to the condition.

Dr. HARRIS recalled the case of Mrs. Reybold, whose uterus was suspended for fifty years. She died at eighty. The senile organ was drawn out into a tongue shape: the uterine attachment was one and a half by three-fourths inch at time of death. The uterus was four and a half inches long, and the vagina was lengthened and cord-like. There had always been a tender spot in the cicatrix, probably from tension.

Dr. KELLY stated, in reply, that he considered the main points which had been raised had been already answered in the paper. He considered these cases as rare, and by no means recommended a resort to section and suspension without first trying every other known expedient likely to relieve, and then only in those cases in which the local disorder causes such pain or disability as to render life a burden. He considered the operation advisable, however, in those cases in which, after removal of the appendages, the flexed organ failed to remain upright when lifted into position. An occasional resort to hysterorrhaphy will not affect the table of recoveries from operation, but will affect the list of patients *cured*, which is not always made so prominent after abdominal section.

W. H. H. GITHENS,
Secretary.

PHILADELPHIA ACADEMY OF SURGERY.

A MEETING of the Philadelphia Academy of Surgery was held December 6, 1886, the President, Dr. D. Hayes Agnew, in the chair.

Dr. Charles W. Dulles read a paper on a case of "Properitoneal Hernia."

DISCUSSION.

Dr. William Hunt: As we know, very curious coincidences happen in surgery. Within the past three weeks Dr. Agnew and I saw a case of the kind described by Dr. Dulles. A physician called on me on a Friday, three or four weeks ago, telling me that he feared that he had overlooked a case of strangulated hernia in a gentleman sick since the previous Monday or Tuesday. The symptoms had excited his suspicion as to the existence of such a condition, but the patient denied that there was any lump in the groin, and refused to permit any examination. I went to see the patient at once, and found a condition of affairs that was new to me, notwithstanding the large number of hernias that I have seen. There was no testicle in the right scrotum, but a lump in the canal proved to be the undescended testicle. Above the testicle was a lump which, while dull on percussion and not gurgling on manipulation, presented such peculiarities that I asked further advice, and Dr. Agnew was called. We then passed an exploring needle, but obtained nothing but bloody serum. An exploratory incision was decided upon. I cut down, and at once, after passing almost entirely through the abdominal wall, reached a mass of omentum. There were no signs of a sac. Underneath this were two or three knuckles of intestine. Passing my finger deeply, I found a stricture corresponding to the internal ring, but formed of tissues much stronger. This was divided, and a large mass of omentum, which was approaching a gangrenous condition, cut off. The intestine was then returned. The man died within twelve hours, but no post-mortem was allowed. This is evidently a case similar to those described to-night. The cause assigned for the refusal to permit an examination in this case was the man's shame on account of the absence of the testicle.

Dr. J. H. Packard: I am not sure whether or not I have understood Dr. Dulles, but my idea of a properitoneal hernia is a condition of things in which a diverticulum of the peritoneum has formed near the inguinal opening, and that this sac, thinned out, may make its way either between the layers of muscles directly under the skin or perhaps directly in front of the peritoneum.

I would also ask if the hernia recorded by Baron might not have been a case of that form of hernia mentioned in the text-books in which there has been a protrusion, then thickening of the wall of the sac, this being followed by a second protrusion?

Is there any record of a case of peritoneal hernia which existed by itself? Has there been any case in which there has been simply a diverticulum of peritoneum, the sac being closed in the ordinary position?

Dr. O. H. Allis: I should like to refer to a case which I had a few years ago. Dr. Packard has spoken of the manner in which a hernia is sometimes formed by the pushing down of a portion of the sac. Some time ago I was called to operate on a patient who had had hernia for years, and who had frequently reduced it. On this occasion he reduced it, but in the course of an hour he found that he had not reduced it properly, and sent for a physician, who, not being able to reduce it, sent for me. I operated, and found it necessary to go deeply. Passing my finger as high as I could, I could just touch the stricture. This I divided, and reduced the hernia. I imagined that in that instance one of the sacs was above Poupart's ligament.

I was called to see a case with Dr. Porter, in which the physician thought that he had reduced a hernia. On operating, a mass of omentum in a gangrenous condition was found lying in the outer opening. While discussing what our further course should be, the tissue slipped into the abdominal cavity. The patient had fecal vomiting for a few days, but eventually recovered. The first case might come under the head of properitoneal hernia made so by the attempts to reduce it.

Dr. C. W. Dulles: In reply to Dr. Packard, I would say that I have met with no recorded case in which properitoneal hernia existed as a simple condition. It has always been a complication of inguinal hernia. In a certain sense, the case described by Dr. Allis would be properitoneal; but this term is only applied to those cases in which the hernia has become properitoneal by a slow process. His case might be called one of properitoneal hernia by force.

From my study of the subject, I would say that it is not a difficult matter for one on his guard to diagnosticate correctly and treat correctly a case of properitoneal hernia. I did not care to go into the proper treatment of these cases; but it is governed by general surgical principles. There are cases on record which have been most successfully treated by an independent laparotomy and drawing the intestine back, instead of pushing it.

A POINT IN THE TREATMENT OF PERITONITIS.

Dr. Charles B. Nancrede: I wish to allude to a point in the after-treatment of such cases as that described by Dr. Dulles. The treatment usually recommended in peritonitis is the use of large doses of opium, and I have myself been in the habit of keeping patients very thoroughly narcotized. If the inflammation comes on gradually, with elevation of temperature, etc., I see no particular disadvantage in treating the case in that way if the patient is seen at frequent intervals. There is, however, a certain number of cases in which the affection comes on in a different way. The temperature is normal, or subnormal in some cases, the heart's action is almost imperceptible, the skin is clammy, and there is a depressed state of both mind and body. In such cases, where there is vaso-motor paresis, to give opium simply because peritonitis is suspected will surely kill the patient; whereas if opium is given in small doses, with positive doses of atropia, especially hypodermically, the patient will react (perhaps to die eventually), and give you the chance for a few days more of treatment of the peritonitis. Again, in the later stages of peritonitis, especially where the temperature does not run high, where tympany comes on, where hypostatic pneumonia appears, and the respiratory and cardiac centres are failing, instead of pushing the opium, it should be stopped and large doses of atropia employed. This stimulates the cardiac and respiratory centres, and gives the patient the benefit of a few more days of treatment. While many are familiar with this principle, yet all do not act upon it. If in the conditions which I have mentioned opium were absolutely withheld, I think the results would be more satisfactory.

Dr. S. W. Gross: In describing his case, Dr. Dulles stated that he had punctured the intestine with a small aspirating needle for the relief of the tympany. In this case the opening remained patulous, although the patient died before peritonitis had time to develop. Nothing could be more injudicious than the use of this procedure in such cases. When in Mexico last spring, I was invited by a distinguished surgeon to witness a post-mortem. The case was one of intestinal obstruction in which large quantities of fluid had been forced into the bowel, and for the relief of the great distention of the abdomen puncturing the intestine with a trocar had been resorted to. There were two strictures of the intestine. The bowel was distended to a degree that I had never before seen. The opening made by the trocar was thoroughly patulous, and fecal matter had extravasated into the peritoneal cavity, the man dying of peritonitis. If any opening is made in these cases, it should be made with the smallest possible instrument.

Dr. J. Henry C. Simes: I have seen one case in which the needle of the ordinary hypodermic syringe was introduced into the intestine. At the autopsy the opening was surrounded by beginning gangrene, and with the greatest ease fecal matter could be forced through the small opening.

The President, Dr. D. Hayes Agnew: Speaking of puncturing of the intestine, I may say that in the case mentioned by Dr. Hunt the needle was introduced for diagnostic purposes. I do not believe in the introduction of a needle, however small, into the intestine for the liberation of gases. I know of no good that comes from this procedure. It is quite possible that in the case mentioned by Dr. Simes there might be some other explanation than that the condition was due simply to the small opening made by the hypodermic needle.

Dr. C. W. Dulles: I punctured the intestine in this case with considerable trepidation, but the condition was an extreme one. I have recorded the fact partly because it serves as a warning against this practice.

Adjourned.

[NOTE.—A correction should be made in the reference (foot-note on page 159, *ante*) to Dr. Nancrede's case of gunshot-wound of the abdomen. The suggestion of Dr. Gross was that septic *intoxication* caused death,—not septic *mortification*, as it appears in type.]

REVIEWS AND BOOK NOTICES.

House-Plants as Sanitary Agents, or the Relation of Growing Vegetation to Health and Disease. Comprising also a Consideration of the Subject of Practical Floriculture, and of the Sanitary Influence of Forests and Plantations. By J. M. Anders, M.D., Ph.D., etc. Philadelphia, J. B. Lippincott Company, 1887. 8vo, cloth, pp. 337.

Growing flowers are welcomed in the sick-room not merely for æsthetic and sentimental reasons, but because they demand sunlight and reasonably pure air; so that they are good company for the invalid. The real amount of our indebtedness to plant-life is very imperfectly understood, and not at all appreciated. Dr. Anders has called attention to a subject which has been almost ignored,—the sanitary relations of house-plants. The usual query is, "Will plants do any harm in the sick-room?" In this book many cases are cited where distinctly therapeutic effects were obtained by a judicious use of vegetation in the sick-room, and this quite exclusive of the moral effect as affording a subject of pleasurable interest to the sufferer. Dr. Anders disposes of the theory that growing plants can give rise to malaria, and reports experiments demonstrating their wholesome influence, both in preventing disease and in restoring health.

Congrès Périodique International des Sciences Médicales. 8me Session. Copenhague, 1884. Compte-Rendu publié au Nom du Bureau par C. Lange, Secrétaire Général. Tomes I., II., III., IV. Copenhague, F. Hegel & Fils, 1886.

The proceedings of the last International Medical Congress are at last published, and form four good-sized octavo volumes, of from 130 to 210 pages each. The papers are valuable and the discussions interesting. The attempt to conciliate conflicting interests by the publication of polyglot discussion in English, French, and German gives the proceedings a peculiar, perhaps unique, character that is not without attraction: we feel, however, that it would be more appropriate to adopt one language, either French or Latin, as the official language of the printed work of the Congress, even though German and English be permitted during the oral discussions.

Transactions of the American Surgical Association. Volume Fourth. Edited by J. Ewing Mears, M.D., Recorder of the Association. Philadelphia, 1886.

A report of the meeting at Washington has already appeared in these pages; the present handsomely-printed volume contains the addresses, essays, and discussions in full. A number of illustrations have been introduced which add to the attractions of the volume, which is not inferior to any of its predecessors in variety or value of its contents.

The works of Professor James E. Garretson have been published in a special edition for holiday gifts. They are put up in sets of four 16mo volumes, handsomely bound in neat vellum cloth, with gilt top and rough edges. These essays afford a healthy intellectual exercise to those who have a philosophic turn, the author possessing the art of vigorous and easy diction and the faculty of keeping the reader's mind on the alert.

NEW REMEDIES AND CLINICAL NOTES.

The Pathology of Infantile Cerebral Paralysis.—In an article reporting four cases of cerebral paralysis in children, Dr. R. Norris Wolfenden makes the following observations upon the pathology of these interesting cases, which, as he justly remarks, is obscure:

"As in infantile spinal paralysis, the motor gray matter is the seat of the lesion,—in the spinal form the anterior horns, in the cerebral the gray cortex. In all old cases of infantile cerebral paralysis Strümpell has found porencephalic defect in the cerebral motor area, the result of an inflammatory process, and thus not *congenital*, that is, due to arrested development. Gaudard considers it a meningo-encephalitis of the motor region of the cerebral cortex, and also allows that it may be due to embolic or thrombotic softening or cerebral hemorrhage. Strümpell says it is always inflammatory, and the nature is indicated by microscopic examination, which resembles the inflammatory microscopic appearance of the spinal gray horns. Wohlmuth found the right hemisphere in one case affected with pachymeningitis, and about one-third its natural size.* It must be remembered that Gowers† has attributed the sudden hemiplegias of childhood to thrombosis of the longitudinal sinus, or veins opening into it. This leads to shrinking and induration of the cortical areas. The question is whether the disease is really a variety of spastic hemiplegia. It seems to me to bear a remarkable resemblance to spinal paralysis, and I cannot resist the thought that it is a similar affection of the cortical area of the brain, as Strümpell affirms. Pathological observations on this point are much required; meanwhile, the question may be considered *sub judice*, with strong probability that the disease is really a newly-described variety of hemiplegia in childhood, pathologically resembling acute spinal paralysis, in that it is an inflammation

* Aerztlicher Verein zu München, 24 Feb., 1886.
† Diseases of Brain, p. 194.

of the motor cells of certain areas of the cerebral cortex, leading to permanent loss of function of the part, due to subsequent atrophy and destruction of this area.

"Of course infantile hemiplegia is very common, but the importance of Strümpell's contention is in recognizing this particular form of hemiplegia in children, clinically so well characterized, as a cortical form of 'essential paralysis' closely allied in its pathology to the spinal disease."—*The Practitioner.*

COCAINE NOT A DANGEROUS TOXIC AGENT.—Dr. W. A. Hammond reported the results of some experiments with cocaine hydrochlorate to the New York Neurological Society, in the course of some remarks upon cocaine and the so-called cocaine-habit. He believed that the injurious effects of coca had been greatly exaggerated: having injected cocaine hypodermically, commencing with one grain, and day by day increasing it until he administered to himself eighteen grains without serious symptoms of poisoning beyond intense exhilaration and subsequent headache. In each of his experiments the diuretic influence was evident. Cases to which he had given the remedy for some time were able to discontinue it abruptly without ill effect; he therefore denied that a cocaine-habit exists which is at all comparable with the opium- or alcohol-habit.—*The Medical Record*, November 20.

NOTES AND QUERIES.

TOXIC SYMPTOMS FROM ATROPINE USED FOR ACUTE CORYZA.

Having been pleased at the prompt relief afforded to two cases of acute coryza by the use of sulphate of atropine, I determined to test its value. Upon seeing Miss E., æt. 25, of a highly excitable nervous organization, suffering with an attack of acute coryza, I ordered sulphate of atropine, gr. $\frac{1}{150}$, which was taken about 10 P.M. In a short time she slept, but in an hour was awakened by dryness of the mouth and a "smothering feeling." The druggist was ordered to furnish two granules, each of gr. $\frac{1}{100}$. As these conditions increased in severity, two hours later, the mother, upon her own responsibility, administered the remaining dose. In a few minutes the patient experienced increasing dryness of the throat, accompanied by a sensation as if the tissues were being forcibly torn apart; the tongue increased in dryness and adhered to the roof of the mouth; the nostrils felt parched and hot; articulation was almost impossible; the pupils were widely dilated; respiration became rapid and shallow, being accompanied by a sensation of imminent suffocation, causing her to sit up and gasp for breath, while there was increased rapidity of the heart's action (pulse 120–140); and the skin was covered with a bright scarlet rash.

In forty-eight hours, after appropriate treatment, the system had regained its usual condition. The coryza was dispelled.

There was no error in preparing the doses, as I was present when the medicine was obtained. Unusual susceptibility to the drug—gr. $\frac{1}{60}$ having been taken—will explain its poisonous effect on this patient.

CHARLES BAUM, M.D.

630 NORTH BROAD STREET,
December 6, 1886.

DR. A. JACOBI, of New York, wishes the fact published that he has resigned from the Committee on the Collective Investigation of Diseases of the International Medical Congress, and that pamphlets and communications relating thereto shall no longer be addressed to him, but to N. S. Davis, M.D., No. 85 Randolph Street, Chicago, Illinois.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 5, 1886, *TO DECEMBER* 18, 1886.

MAJOR A. A. WOODHULL, SURGEON.—Ordered for duty at post of Fort Leavenworth, Kansas. S. O. 138, Department of the Missouri, December 3, 1886.

MAJOR JOHN W. WILLIAMS, SURGEON.—Ordered for duty at Jackson Barracks, Louisiana. S. O. 205, Division of the Atlantic, December 14, 1886.

MAJOR B. F. POPE, SURGEON.—Relieved from duty in the office of the Surgeon-General of the Army, and will report in person to the president of the Army Medical Examining Board in New York City, for duty as member and recorder of the board. S. O. 285, A. G. O., December 9, 1886.

BENJAMIN F. POPE, MAJOR AND SURGEON.—So much of S. O. 285, A. G. O., December 9, 1886, as directs him to report in person to the president of the Army Medical Examining Board, New York City, for duty as member and recorder of the board, is revoked. S. O. 287, A. G. O., December 11, 1886.

CAPTAIN JOSEPH K. CORSON, ASSISTANT-SURGEON.—Leave of absence extended seven days. S. O. 288, A. G. O., December 13, 1886.

CAPTAIN F. C. AINSWORTH, ASSISTANT-SURGEON.—Will repair to this city and report in person to the Secretary of War, and on completion of the duty which may be required of him will return to his station (New York City). S. O. 280, A. G. O., December 3, 1886.

CAPTAIN FRED. C. AINSWORTH, ASSISTANT-SURGEON.—Relieved from duty as recorder of the Army Medical Examining Board, New York City, and ordered to report in person to the Surgeon-General of the Army for duty in his office. S. O. 282, A. G. O., December 6, 1886.

CAPTAIN H. S. TURRILL, ASSISTANT-SURGEON.—Ordered for duty as post-surgeon, Fort Spokane, Washington Territory. S. O. 209, Department of the Columbia, November 29, 1886.

CAPTAIN EDWARD C. CARTER, ASSISTANT-SURGEON.—Leave of absence extended six months. S. O. 281, A. G. O., December 4, 1886.

FIRST-LIEUTENANT CHARLES C. BARROWS, ASSISTANT-SURGEON.—Granted leave of absence for two months, to take effect when his services can be spared by his post-commander. S. O. 285, A. G. O., December 9, 1886.

FIRST-LIEUTENANT GEORGE F. WILSON, ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply to Headquarters, Division of the Missouri, for an extension of twenty days,—to take effect about December 15, 1886. S. O. 125, Department of Dakota, December 1, 1886.

FIRST-LIEUTENANT R. R. BALL, ASSISTANT-SURGEON.—Ordered for duty at Fort Riley, Kansas. S. O. 144, Department of the Missouri, December 13, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FOR THE WEEK ENDING DECEMBER 11, 1886.

PASSED ASSISTANT-SURGEON H. T. PERCY, U.S.N.—Ordered to Naval Academy, Annapolis, Maryland.

PASSED ASSISTANT-SURGEON ERNEST NESFLEET, U.S.N.—Granted three months' sick-leave.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED DECEMBER 18, 1886.

BANKS, C. E., PASSED ASSISTANT-SURGEON.—Granted leave of absence for twelve days, December 16, 1886.

CARRINGTON, P. M., ASSISTANT-SURGEON.—Granted leave of absence for fifteen days, December 6, 1886.

WILLIAMS, L. L., ASSISTANT-SURGEON.—Upon expiration of leave, to proceed to Boston, Massachusetts, for duty, December 17, 1886.

COLLEGE OF SURGEONS OF ENGLAND

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, JANUARY 8, 1887.

COMMEMORATIVE ADDRESS

Delivered January 3, 1887, at the

CENTENNIAL ANNIVERSARY OF THE INSTITUTION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

BY S. WEIR MITCHELL, M.D., LL.D.,
President of the College.

WE are met this evening to commemorate the hundredth birthday of the oldest medical society in America which is not a State organization. New Jersey and Massachusetts have State societies of older date, which of necessity met rarely, and were chiefly meant to give unity, force, and discipline to a profession the members of which were widely scattered over a thinly-peopled country.

One hundred years ago the grave and kindly man whose portrait hangs above me at our meetings met the Fellows of this ancient College as their first President.

In words which quaintly represent to-day my own feelings, John Redman expressed his sense of the honor then conferred upon him and of the responsibility created by such an audience; "for," said he, "when I look around me, I see so many gentlemen of character for learning, ingenuity, and integrity in the profession and practice of physick, and some whose talents have early called them forth into publick notice and offices of dignity in the medical line, and who have conducted therein for many years so much to their own reputation and to the advancement and satisfaction of their pupils and of their fellow-citizens."

At the close of his address he confesses that his mind has taken a more serious turn, and says, "I think it is very becoming in us at the commencement of this our institution to acknowledge the Supreme Being to be our sovereign Lord and Ruler," and thus goes on into a simple and straightforward prayer, "that through all the days of this College they who sat about and all who are to come publickly and privately serve their generation faithfully, according to God's will, that they may find rewards beyond the grave."

When John Redman thus seriously addressed the founders of what he called "a collegiate society" he was sixty-five years of age. He was born forty-one years after William Penn laid out this city. The men he so feelingly counselled were all his juniors. He looked back over the larger part of a century, during which his new-born country had leaped to sturdy life and set an example that had helped to bring unthought-of changes to its great European ally,—a century of disturbing political and social thought, fertile in revolutionary activities.

To understand the men over whom he presided, to comprehend the inheritance of examples they left us, to realize, above all, how peculiar have been the relations of the physician to the social and political existence of Philadelphia, it is necessary to look back through the century which preceded the foundation of this College.

The history of any profession in connection with the progress and growth of a new country is of the utmost interest, and of no profession is this more true than of ours. The bar, the army, the navy, and, in other lands, the church, have distinct natural relations to the government, but the physician has none, and in monarchial countries this fact has served to create for him annoying social limitations which are but too slowly fading as communities grow into intelligent disregard of feudal traditions. His position in any community is a fair test of its good sense. But in new lands, peopled by the self-selection of the fittest, by those who have the courage of enterprise, and the mental and moral outfit to win for it success, the physician is sure to take and keep the highest place, and to find open to him more easily than to others wealth, social place, and, if he desire it, the higher service of the State. Nowhere was this more true than in this city. In New England the clergy were for a long time dominant. In New York, then, as now, commercial success was the surest road to social position. South of us it was the landholder who ruled with undisputed sway. But in this city—I may say in this State—from the first settlement until to-day the physician has held an almost unquestioned and somewhat curious pre-eminence. He is, and always has been, relatively a more broadly-important personage here than elsewhere.

If this be not as clear to you as it is to me, let me remind you that in every legislature of this Commonwealth you will find a dozen members of our profession who have for a time taken up the duties of lawgivers, intending to return again to their practice. I observe on the list of our Fellows to-day many men—and they are of our best—who have been or who are directors of insurance companies or saving-funds, or even of banks, a thing almost unheard of in cities where the lower civilization of commerce is dominant. You will find them also, in unusual numbers, on our collegiate boards. Our great charities are never without some of them in their councils, and the Philadelphia Library is obliged, under the will of James Rush, to have in its direction three physicians. In our hospital boards, and still more largely in our learned societies, they are equally well represented.

Says a learned historian, writing of the

Philadelphia of 1828, "Nothing struck me so much as the social force and influence of the physicians. I was familiar with other cities, and nowhere else did they seem to me to be so distinctly the leaders of social life."

The exceptional position which we occupy here is in a large measure due to the good fortune which early in our history directed to these shores a remarkable group of physicians, the friends and co-religionists of Penn.

As I am chiefly addressing Pennsylvanians, I shall not venture to say much of men whose names are still familiar. I desire, however, to show what breadth of liberty they had to do things which nowadays would scarcely be regarded as within the legitimate career of the largest-minded physician. Edward Jones, chirurgeon, came over in 1682. His father-in-law, Thomas Wynne, set sail in the "Welcome," with his friend William Penn, in that same August. These were both physicians of gentle breeding and of the best education their day could offer. Thomas Wynne was an active practitioner of physick, and yet found time to become President of the first Assembly which met in the province, and in which sat also his son-in-law Jones. Both of these men lived to hold many offices of political trust and honor in their adopted country.

Next in our medical genealogy comes Thomas Lloyd. There is what was called in Friends' phraseology a testimony* concerning him, which, heard pleasantly across the turmoil of nearly two centuries, tells how that "he had a great practice, . . . and generally good success, whereby it was often his lot to be amongst many of account in the world. . . . Yet, being a man of tender spirit, he was conscientiously careful over his patients, whether poor or rich."

In the new land he sought for conscience' sake he was still for a while a physician. How, think you, did he find time to act as Deputy-Governor under Penn, President of Council, Keeper of the Great Seal of the Commonwealth? Apparently the good and great William Penn took care of his physician, for we hear that his friend Dr. Griffith Owen held the posts of Member of Assembly, Deputy-Master of the Rolls, and Commissioner of Property.

The early part of the next century was as fortunate. Lloyd Zachary, the grandson of that accomplished physician and trusted ruler, Lloyd, was the first physician elected to the Pennsylvania Hospital, and was what we would call Port Physician in 1725. He shared this duty with Thomas Græme, a Scotch physician, who arrived with Governor Keith in 1715. Besides being thrown into large practice by the death of Griffith Owen, this gentleman was at various times Naval Officer, a Councillor, Master in Chancery, and at last Chief Justice of the Supreme Court, for which we may note that he received fifty pounds a year. He was the first president and the founder of the now ancient and still useful St. Andrew's Society for giving aid to destitute Scotchmen, assisted to create the Philosophical Society, was with Zachary, the two Bonds, Moore, Cadwalader, and Redman, of the first staff of the Pennsylvania Hospital, and died in 1772, Collector of the Port. On his tombstone, in Christ Church yard, it is said of him, and it would seem with justice, that

> "The soul that lived within this crumbling dust
> In every act was eminently just;
> Peaceful through life, as peaceful, too, in death,
> Without one pang he rendered back his breath."

The men I have here so briefly described were, with the exception of the last, of the Society of Friends; Græme was of the Church of England. The great struggle between the Presbyterian settlers of the interior of the State and the followers of Penn was now in full tide. Already other sects than those of Penn began to be prominent, and henceforward we find physicians of eminence who were not of the creed of Fox, but neither in the seventeenth nor the eighteenth century do we observe in Pennsylvania what was very common in early New England and New Jersey,—men doubly occupied as physicians and clergymen.

To the new group of men belong, also, the two Kearsleys, to one of whom, John, a member of the Assembly, we owe the interesting spire of Christ Church and the endowment of Christ Church Hospital for Reduced Women. Kearsley's pupils—or, as was then said, apprentices—were all natives of the country, and among them were Zachary, Cadwalader, William Shippen, Sr., the Bonds, Cadwalader Evans, Redman, Bard, and John Kearsley, Jr. Bard speaks with energetic disgust of his master's exactions. The pupil was constantly subject to his orders. He carried medicines to the sick, or prepared drugs for use by his master in his daily rounds; he made fires, kept the office clean, and did other less agreeable duties commonly devolving nowadays on servants.

William Shippen, a founder of the College of New Jersey, was, with Redman, the only one of Kearsley's pupils alive in Philadelphia when this College was instituted. An active Presbyterian, he was a trustee of Princeton College and of the College of Philadelphia, vice-president of the Philosophical Society, one of the staff of the Hospital, and, later in life, a member of the Continental Congress.

Thomas Cadwalader was a descendant of Wynne and Edward Jones, and, like the men of his day, active in scientific societies, hospital work, and the stormy politics of his time. Unlike the Bonds and Kearsley, he was a stanch Whig, and his two sons, John and

* Levick, J. J., "Early Physicians of Philadelphia," etc.

Lambert, were both soldiers of distinction. His sedate visage hangs in your hall to justify the words in which John Redman regretted that he had not lived long enough to become the first officer of this body. "One," he says, "on whose age, character, and reputation for medical ability and respectable deportment to and among us, as well as his generous, just, and benevolent temper of mind and great acquaintance with books and men and things, and proper attention to times and seasons, would, I am persuaded, have pointed him out as our first object." He is sure that his name will readily occur to the Fellows. "Nor need I mention it," he adds, "but that I naturally recollect with pleasure the name of our worthy and well-respected brother, and my much esteemed friend, Thomas Cadwalader."

He grieves, in like manner, that Thomas Bond could not, also, have preceded him in office, "a man of judgment and skill, of indefatigable assiduity to the last in the practice of physick and surgery."

I should have found it difficult to say less as regards the notable personages who came and went on the scene of our Colonial history, and who brought to their medical work the tastes, manners, and education of gentlemen, and to its completeness high-minded sense of duty. It was needful that I spoke of them in order to show how perfect has been the good fortune which, from the day when the "Welcome" brought us Thomas Wynne up to the present hour, has failed not to give us like men, gifted with like intellectual qualities, holding the same lofty traditions of honor and industry, ready to take up our unending task whenever an older and wearied generation laid it down.

The century was in its last third. A new group of physicians, nearly all young or in early middle age, and trained in an eventful war, had come upon the stage. The city contained about forty-five thousand people. It was the seat of government and of the largest social life the land afforded. Still predominant in commerce, it was also active in education and science. The College of Philadelphia had been for a time suppressed, the University had been medically organized, the Federal Constitution was in debate, and Washington, a man of fifty-six years, was resident in Philadelphia. Fitch was constructing his first steamboat.

Who first suggested the formation of this College is unknown, but, as many of our Fellows were educated in Edinburgh, it is likely enough that the success of its Society, which dated from 1733, may have led them to imitate it here. I have myself seen on its diploma the name of "Caspar Wistar Præses annuus."

We know as little of the earlier steps taken towards the foundation of this College. John Redman, your first President, says that "at the first meeting to organize ourselves by choosing proper officers and members so as to constitute a body," he was elected President. He adds, "I went home under a strong impression of the weight both of the office and my obligations to you." Then he tells us that he was unable to attend the next meeting, and apparently it is at a third meeting that he delivers the address from which I have already quoted. Its faded ink and formal, patient writing seem to take one back to a less hurried era, and speak eloquently of the busy years which have come and gone since my serious-minded predecessor looked forward hopefully anticipating your future usefulness.

It would seem that the College was organized some time in 1786, but as to this we have no record other than that just mentioned. The first meeting of which we have a minute took place January 2, 1787, and to this date we have always referred as our natal day.

On that 2d of January, 1787, in the evening, in a little house used by the University, and known as Surgeons' Hall, on Fifth Street south of Library, assembled a portion of the notable group of men who then constituted this College. By the dim light of candles, for which I have found the modest bill, clad after the fashion of the day, some in Quaker dress and some in knee-breeches, silk stockings, and low shoes with buckles, most of them carrying, I fancy, the gold-headed cane and the meditative snuff box, some with queues or powdered wigs, a fading fashion, were John Jones, William Shippen, Jr., Adam Kuhn, Benjamin Rush, Thomas Parke, Gerardus Clarkson, Samuel Duffield, James Hutchinson, William W. Smith, Andrew Ross, William Clarkson, James Hall, William Currie.

The full roll of Fellows and junior Fellows in January, 1787, adds the names of John Redman, John Morgan, George Glentworth, Abraham Chovet, Benjamin Say, Samuel Powel Griffitts, Benjamin Duffield, John Morris, John Carson, John Foulke, Robert Harris.

Before our charter was obtained in 1789, there were added Nathan Dorsey, John R. B. Rodgers, Caspar Wistar, Jr., James Cuningham, Charles Moore, Michael Leib, John H. Gibbons.

They were in all twenty-four when they met in January, 1787, and thirty-one when they were incorporated in 1789. Only three of their names are to-day represented on our present list; but many more are familiar to your ears, and, if we include the men I have previously mentioned, you will find that a large share of the best-known families of our city trace their lineage from one or other of this memorable group. It would, in fact, be easy to give you a long catalogue of families distinguished in our national and local history, or in our social life, who inherit the blood of one or more of the physicians I have named

or have yet to name; but, as some of those here present may have the misfortune not to be able to claim the honor of medical ancestry, I generously refrain.

The portraits of many of these notable personages ornament our halls, and tell in their ruddy complexions of men who lived much out of doors and often in the saddle, and illustrate the changes which time is making in the physical conditions of our race. Here are descendants of the settlers who, armed only with the courage of good intention, came to the wilderness with Penn, or followed soon after. Welsh or English nearly all of them, but two represent the German element; only four have middle names, as to which a curious change is seen in the later years.

The older men generally sign first. The President was sixty-five; Jones, fifty-eight; Morgan, Shippen, and Kuhn, each fifty-one.

These were physicians who assisted at the troublous birth of a great nation. I fancy that I can see in their resolute faces the lines left by the sorrows and trials of those eventful years when they rode with the great Virginian and shared with him the hardships of doubtful campaigns and the triumphs of Princeton and Yorktown. Among them were the friends and physicians of Washington, Franklin, Hamilton, Jefferson, and Adams. They held to their medical opinions, as we shall see, with the same absolute belief that controlled their political actions, and were nearly as ready to fight for the one as for the other. As to their medical ancestry, the best of them had been educated at Edinburgh, which school is the parent of our University. Genealogically, we might speak of our College and of the University as children of Edinburgh and grandchildren of Leyden.

Linger with me a little, and learn who and what were these our medical forefathers,—the men who had won fame and matured character on the field and in the hospital wherewith to face the yet darker hours of the deadly plague so soon to thin their ranks.

The most illustrious of our profession are not always the most lovable. Your first President, John Redman, was a man whom all men respected and all men loved. He spent a year at Edinburgh, was graduated at Leyden, in 1748, under Albinus, and returned home to practise finally only medicine, declining midwifery and surgery. In his medical creed he was a sturdy follower of Sydenham. Like the most of his fellows, he bled without hesitation and believed that the American needed more positive treatment than his degenerate British ancestor. Except his thesis on abortion, a defence of inoculation, and his excellent account of the yellow fever of 1764, he left little behind him. A man gentle without lacking force, religious without a trace of bigotry, and finding in his faith only larger reasons for cheerfulness. Quick of temper and as quick to regret it; punctual, charitable, exact, a type of what the practice of our profession makes out of the best characters, he constantly declined political place. We are told "that he suspended pain by his soothing manner or chased it away by his conversation." One would like to possess the secret of this anæsthetic kindness. He died in 1808, at the age of eighty-six, and, we are told, was mourned and missed most by the destitute, being like that physician of whom Somervile says,—

> "For well thy soul can understand,
> The poor man's call is God's command."

John Jones, our first Vice-President, was of another type. His two grandfathers were Edward Jones and Thomas Wynne. He went abroad early, and again at a later date, and became the warm friend of Hunter and Pott. In 1755 he served with Sir William Johnson in the French War, settled in New York, and left it when it was occupied by the British. For a time he sat in the Senate of New York, then entered the army, and in 1778 settled here, where he succeeded Redman in the hospital, became the first president of the Humane Society, and was physician to the Dispensary until his death in 1791. We owe to him the first American book on surgery, in 1775. He dedicated it to Cadwalader, and says, "If I cannot cure the fatal disease of my unfortunate country, I can at least pour a little balm into her bleeding wounds."

John Jones was of the Society of Friends, and lies, since 1791, after their fashion, in a nameless grave under the maples in their Arch Street burial-ground. He was a man tranquil of temper, easy and polite, fond of poetry and belles-lettres; a surgeon so expert in lithotomy that he frequently operated for stone in a minute and a half. For this malady he attended Franklin, of whose philosophic cheerfulness he has left a clear account. In 1790 he went to New York to consult in the case of Washington, who suffered at that time from some acute disease of the lungs.

I pause to add that another of our Fellows, Plunket Glentworth, son of the founder George, also attended Washington in Philadelphia in 1797.* I have seen a letter to John Lewis, in which the illustrious patient says of this physician, "No nobler man or more skilful physician ever lived," and calls him his "estimable friend,"—almost the sole record of this Glentworth,—the friend of Washington.

Of John Morgan, one can only speak with admiration. There is in this State a portrait of him by Angelica Kauffman, and the excellent copy in our hall has all the charm of distinction and manly beauty. The student and friend of Hunter and the famous Hewson,

* The Hon. George Bancroft tells me that about this date Washington underwent an operation for some rectal disease, but as to its nature we know nothing further.

he knew well Voltaire and the great Morgagni, who gave him the noble copy of his works, now in our library, inscribing on the first page

"Viro experientissimo et humanissimo
D°. D. Joanni Morgan.
Auctor."

In his thesis on pus, Morgan anticipated Hunter's theory of its origin from the blood. He came home, aged twenty-nine years, a Graduate in Medicine of Edinburgh, Member of the French Academy of Surgery, Fellow of the Royal Society, and with the honors of the Colleges of Edinburgh and London, to found the University of Pennsylvania, and to serve as Director-General and Physician-in-Chief of the army in 1775. He lies now in old St. Peter's churchyard. His dignified vindication of his army career is almost all we have left us of a brilliant and well-loved gentleman.

To speak of William Shippen, Jr., would be almost to repeat what I have said of his friend Morgan. His friends in London were the same, and also, we may add, the high-minded Fothergill and Sir John Pringle. The war made him Director-General, and I may pause to add that Potts, a Pennsylvanian, and Tilton, one of our earliest associate Fellows, held a like position. William Shippen was our second President, a handsome man, gay and yet dignified, so amiable that through life he is said to have made no foes,—a doubtful formula of praise. He left a great name as a happy lecturer, and was the first of that remarkable series of anatomical demonstrators whose names are so familiar to us all.

Adam Kuhn, son of the physician and magistrate, Adam Smith Kuhn, came home in 1768 from his European studies at Edinburgh and Upsal. I find in the *Eclectic Repertory*, vol. viii., a number of very pleasant and interesting letters from Linnæus to the father and to the son. He speaks of the latter as an amiable, correct young man, beloved of all, and for whom he cherished a paternal affection. The younger physician he directly addresses in after-days as his dear friend, and, in letters simple, affectionate, and delightfully full of chatty remarks about plants and animal life and gossip of domestic affairs, calls him his cherished son; speaks of his engaging deportment, his unwearied ardor in cultivating science. In 1772 he refers apparently to having named a plant after his young friend, and says, "I am yours while I live." There must be more of these genial letters. In their pages flowers seem to bloom and humming-birds to flutter as the great naturalist, with gentle envy, pictures the wealth of plant and animal life awaiting his pupil's study in distant Pennsylvania. The daily needs of life may have rendered the pursuit of science difficult to Kuhn. He lectured in 1768, one year, on botany, then on materia medica twenty-one years, and in 1789 became professor of theory and practice in the University, was our third President in 1808, and died in 1817. He left scarce a trace behind him; but no one can read his manuscript lectures, now in our library, without a full sense that the world lost something by the indifference or want of ambition of this learned physician.

With reverent doubt of my powers to do justice to the greatest physician this country has produced, I approach the task of briefly recalling to your memories the vivid and emphatic personality of Benjamin Rush. His life invites a less hasty biographer, and is full of such seeming contradictions as can only be explained by the belief that the earnest, decisive, and mutinous nature of a man proud rather than conceited got the better of the principles by which he honestly strove to guide his conduct. That he won at last in this contest was shown by the grief with which a nation mourned his death, when the poor in crowds besought a sight of his face, or, at least, to touch his coffin. Look at his portrait by Sully in our hall. It has the scholar's hands, the largely-modelled head, the contemplative blue eyes of the observer, the nose and chin strong, firmness in the mouth, and a trace of too critical tendencies in the droop of the lines of the lips, withal a general expression of tranquil benevolence, a face like the man's life and character, full of dissimilars, with a grand total of good.

How shall I briefly bring before you the career of this restless being? Relentless energy drove him through a life in which ardent sense of duty, large-minded philanthropy, love of country, devotion to his art and its science, immense belief in himself, were the motives to industry, which made note-books the companions of his student youth, and which failed not until the pen fell from a hand enfeebled by the close approach of death.

He was a statesman, a scholar, an army surgeon, a punctual and careful physician, an actively religious man, a far-seeing and courageous philanthropist, and a sanitarian far in advance of his day. These are what I might call four careers, in all of which he excelled unaided by secretaries or modern means of condensing and relegating labor: one such suffices most men. He was a member of every important political assembly which met in this State while he lived. When timid men fell out of the Continental Congress, he was elected to that body, that he might sign the Declaration of Independence, and was the only practising physician whose name is on that energetic arraignment of the Crown. I have neither time nor desire to speak of his relations to Washington. He criticised him with his usual courage and with a severity in which at that time he was not alone, and, although later in life he somewhat relented, he never

quite forgot the bitterness which arose out of his too famous letter, and to the end of his days looked upon the great leader as one not above the judgment of his fellows. As regards the patriotism of Rush there can be no doubt. It approached the earnestness of religion, and its very intensity made him unhappy and critical when others seemed to him to be showing that want of energy which in the first years of the war he thought was seen in the Fabian policy of Washington.

Rush was surgeon-general to the Middle Department, and later surgeon general, and served faithfully in the New Jersey campaign and in the dreary camp at Valley Forge. He resigned in 1778, after his difficulty with his chief, and declined pay for his services.

As a broad-minded philanthropist, I view him with wonder. The higher education of women he urged as a special need of a Republic, and as boldly wrote of public punishments and against the penalty of death. With like courage he denounced slavery, or turned to demand legislation against the abuse of alcohol, or to implore care in the use of this agent in disease, and, although a scholarly man, eloquently represented the waste of time in the too general study by the young of the classical tongues.

On his medical career I cannot linger. His views as to bleeding were extreme. They were greatly modified in his latter years, but have been misrepresented by the enmity his positive nature excited, and can be fitly judged, not by his occasional vigor of statement, but also by the many tampering remarks to be found in his works. His ideas on the contagion of yellow fever and its domestic origin excited the hostility of commerce, and embittered his existence; but, although as to the former he changed his beliefs later in life, as to the latter he seems never to have faltered.

I presume that he held his opinions tenaciously, and was so conscious of his own general superiority to those about him, that he found it hard to weigh their reasons justly. He says, "I early discovered that it was impossible for me, by any reasonings, to change the practice of some of my brethren." Then he adds, "humanity was therefore on the side of leaving them to themselves, because what is done in these consultations is the ineffectual result of neutralized opinions; for the extremity of *wrong* in medicine, as in morals and government, is often a less mischief than that mixture of *right* and wrong which serves, by palliating, to perpetuate evil." How interesting is this irritable confession, which tells so much more of the man than he meant to put into it! Let me add, as a thoughtful physician, that no one can read what he wrote—and I have read most of it—without a strong sense of his sagacious and intelligent originality, and admiration of his clear and often fervid style. His work on insanity is a masterpiece. A recent English writer calls his book on "the bilious remitting yellow fever" a wonder, and says of that remarkable description of his sensations during the height of the epidemic, "it is as if he were talking to you, a ghostly whispering through a veil of nine-tenths of a century." He has been called the American Sydenham. He was not, as I see it, so great a physician, but, taking his whole career,—and both were earnest republicans,—Rush was the larger personage, and surely, next to Franklin, the greatest citizen of Pennsylvania.*

His bitterest foes are best remembered because of the man they reviled. Even before death came to heal all wounds, he stood where few men have stood in the estimate of men. He could not but feel this tribute. It gentled the positive and ardent nature, once ready to cross swords with all who dared to differ. He says, "I was once an aristocrat, then a democrat, now I am a Christocrat." Certain of his words should have been placed on his tombstone. With them we may leave him to his repose near the yet greater Franklin. "Posterity," he says, "is to the physician what the day of judgment is to the Christian."

Still among honored Philadelphia names we find next that of Gerardus Clarkson, chief of the founders of the Episcopal Academy, and brother of the Mathew Clarkson, emigrant from provincial New York to this gayer capital, who earned as mayor, in the yellow fever of 1793, a character for manly courage and self-possessed official calmness.

Benjamin Say, who comes next on our list, produced no great work, except his son, the eminent naturalist.

James Hutchinson was the ancestor of our honorary librarian, and, like him, a trustee of the University. There is a pleasant letter extant of the date of 1776, in which Fothergill recommends him to the Pennsylvania Hospital as a trained surgeon and a man of "unblemished character." He had a good deal to do with the union of the College and University in 1791. Like most of our first Fellows, he was a member of the Anti-Slavery Society. It is told of him that when the ship on which he came home from Europe was chased by a British cruiser, he escaped to the coast in an open boat under a heavy fire, to save the despatches Franklin had confided to his care. In 1771 Hutchinson was appointed by Shippen Senior Surgeon to the Flying Hospital of the Middle Department, and in the same year became Director of the Hospitals, Physician- and Surgeon-General of the

* Rush left letters, diaries, and also biographic memoirs of his contemporaries, without which no man can fitly judge him or them. Friends, relatives, and executors have been chary of publishing these records. Some of them I have read, and I think it only just to a great man that we should know all that there is of him to know. He was too great, too productive, too various, to lose esteem on account of anything he may have said or written of Washington.

Militia of the Commonwealth of Pennsylvania. He lived to serve through the war, and to become distinguished as a professor, to hold many posts of public trust, and to die of yellow fever in 1793.

George Glentworth, who comes next, was Senior Physician and Surgeon of the General Hospital of the United States, from 1777 to 1780. He, too, declined pay. It was he who extracted the bullet received by Lafayette at Brandywine fight, at the Indian Queen Tavern in Third Street. He lies now near the street in St. Paul's churchyard.

Of the cynical and merry Tory, Abraham Chovet, there is little to say. Dr. Physick told my father that, while living in London, Chovet tried to save a too adventurous gentleman, about to be hanged for highway-robbery, by opening his trachea before the hangman operated. The patient was rapidly removed after the execution, and is said to have spoken. A queer tale, but worth the telling. As the government lacked due appreciation of this valuable experiment, Chovet brought his queer Voltairian visage to America. You may see it yet in our library.

William Currie left theology for medicine, and served in the war. He is known chiefly by his excellent essays on climate and on yellow fever, and his support of the doctrine of its foreign origin as against Rush, with whom he agreed as regards the question of contagion. In his essays Currie wrote temperately of the matter, and without personalities.

I observe that this writer now and then speaks of the number of pulse-beats, and says the frequent pulse is the weak pulse. Numeration of the heart-beat is very rare in the writings of the last century, and is exceptionally found between the reign of Anne, when Sir John Floyer wrote his book upon it, and the year 1820, when French observers again called attention to its value. Occasional references to the number of the pulse are also found in Rush, but they are, on the whole, uncommon.

Men like ourselves know how hard it is to live up to the best standards of medical duty; know, also, what temptations, intellectual and moral, positive and negative, assail us all, and can understand the value and beauty of certain characters, which, like surely-guided ships, have left no permanent trace behind them, on life's great seas, of their direct and absolute devotion to duty.

Of this precious type was Samuel Powel Griffitts. He wrote little, although an editor of the *Eclectic Repertory*. All that he has left us is a paper in favor of vaccination, and an essay to prove that yellow fever, as a rule, does not attack a second time. He believed it contagious and of imported origin. The sanitary and philanthropic plans of Rush he heartily aided. In the battle with slavery and the penal code and against the abuse of alcohol, Griffitts was a steady worker; whilst the Humane Society, the Dispensary, the Friends' Asylum for the Insane, and the French refugees found in him a constant helper. But wherever he went and in whatever he did peace and gentleness were around about him, so that in every relation of life men and women eagerly trusted this simple, straightforward, intelligent, unambitious man. It is told of him that in forty years he scarcely ever missed his daily visit to the Dispensary, where he met, relieved, and counselled the poor. With one hand, it may be said, he distributed the bounty which his fellow-citizens intrusted to his care to the refugees from St. Domingo, while with the other he was busy sending vaccine virus to their revolted slaves. To the last day of his life he walked our streets in all weathers, averse to the use of a carriage, and thus, punctual, industrious, carrying into every vital relation trustful, unobtrusive religion, this kindliest of men, forgetful of no duty, died abruptly, escaping the pangs he had so often seen in others.

The peaceful Griffitts had, I believe, no relation to the War of Independence, but Benjamin Duffield was, like many other of our Fellows, an army surgeon. In the pest-house at Bush Hill he did manly service in 1793. A hospitable man, of genial humor; both wise and witty, it is said. The familiar seal of the College was probably of his devising, as he was chairman of the committee on this matter in 1787.

Of John Carson, born in 1752, little is known. He was a long time Surgeon to the City Troop, one of the founders of the Dispensary, Professor of Chemistry in the University after the death of Hutchinson, but died in 1794, before he had given a lecture.

Caspar Wistar, Jr., is a more familiar name. Like Rush, there is much of the man's life on record in the portrait by Otis, as the least observant may see. The face is strong and intellectual, the mouth large and full of good humor and mirth, the chin positive, a face thoughtful above, and below alive with promise of genial companionship. He could have been but sixteen when we hear of him as active in helping the wounded after the indecisive fight at Germantown.

He was graduated at Edinburgh in 1786, and left that city President of the Royal Medical Society, and with the warm friendship of Cullen, who later sent him his portrait, and was his frequent correspondent. He must have been the youngest of our corporators, as he was elected to the College in April, 1787, and was then but twenty-six years old. Two years after, he became Professor of Chemistry in the College of Philadelphia; he was made Adjunct-Professor of Anatomy, Surgery, and Midwifery in 1792, and in 1808 succeeded Shippen at the University in the Chair of Anatomy. Men spoke of him as a great teacher. He fortunately combined full

knowledge with fluency and intense interest in what he was teaching. His System of Anatomy, published in 1811, was our first native treatise on that subject.

He followed Rush as President of the Anti-Slavery Society, and Jefferson as President of the Philosophical. If a man's friends be in some sense a description of the man, among his were Humboldt, Michaux, Soemmering and Camper, Cullen, Hope, Jefferson, Warren, and Correa, the cynical and amusing Portuguese minister. You can see from these names that science occupied him, and especially anatomy, that the practical aspects of his profession were not forgotten, and that he was at home among those whose talk left to their surviving contemporaries vivid memories of an unusual social era. He is known still to most of us as the founder of the Wistar Parties, which owed much of their later social vitality to the hospitable houses of the leaders of our profession. When I was a young man and Wistar was long since in his grave, we were still familiar with the worn card of invitation which carried his vigorous profile with its formal queue from simpler days to those of champagne and terrapin, and until the fierce quarrels of the great war broke up this gay and joyous company. It was wickedly said that the doctors profited by those noble suppers. Even in their luxurious decadence they were delightful. Men who came to eat remained to chat. They left to me at least a gallery of pleasant portraits of some whose living talk would have made that good founder happy. Hear how Thackeray mourns a dead friend. "There will be," he says, "no more Whister parties for him. Will Whister himself, hospitable, pig-tailed shade, welcome him to Hades? and will they sit down—no, stand up, to a ghostly supper, devouring the ἰφθιμους ψυχας (the mighty souls) of oysters and all sorts of birds?" *

I have dwelt on this aspect of a full and wholesome, learned and useful life, because it well illustrates the social prominence of the Philadelphia physician. We may leave him with the words in which another described him: "Decorous, suave, honorable, and courteous, he forgot nothing except injuries."

Michael Leib, born in 1759, was the last Fellow of importance elected previous to our incorporation in 1789. His name occurs with honorable mention in the yellow fever records, but he left our profession early and became a brilliant leader in the Democratic party, and filled in turn the post of member of Assembly, and of the United States House of Representatives, and at last went to Congress as Senator. His great war speech of 1812 was long remembered, and he is said to have been for many years the political dictator of Philadelphia. He died in 1822.

* Haud immemor, p. 8. William B. Reed, 1864, Philadelphia.

The earlier Constitution was signed by Senior and Junior Fellows, but in August, 1787, it was readopted in a modified form, and thenceforward the appellation "junior" disappears, and we have only Fellows and Associate Fellows, and, very much later, Corresponding Members.

Up to its incorporation in 1789, the College was busy with private and public affairs. It adopted a seal, and substituted for *non sibi sed alii*, as proposed, *non sibi sed toti*.

It urged the legislature to create a botanic garden and public baths, and to limit the use of ardent spirits, wisely pointing out their hurtfulness, declaring them destructive to life and health, and as tending equally to dishonor character as a nation and to degrade our species. "They," the Fellows, "believe to be without foundation the prevalent idea as to use of spirits in heat and cold, and think malt liquors and cyder might be substituted."

The first effort towards a pharmacopœia was made in April, 1787, and the College ordered a committee to digest the business. This effort was, I believe, the first made in America in this direction. It was never long out of sight, but the digestion was laborious and incomplete until the Pharmacopœia Convention met in 1820.

The germ of our ethical code is to be found in April, 1788, when it was decided that

"To promote order and unity in the practice of medicine, it is agreed by the Fellows of this College that they will not attend or prescribe for any patient who hath previously employed any other Fellow of the College in the same illness, unless it be in consultation with the first physician or in case of sudden emergency, when the said physician is not present;" and then follow directions as to the conduct of consultations.

What was to become of the unlucky patient under this stringent rule does not appear. But codes of conduct, however needful, are difficult so to frame as to cover all contingencies, and the legislation of individual common sense usually intervenes to correct their too absurd application. The larger ethical code, founded chiefly on that of Percival, was accepted by the College in 1843.

In these early days the only death-record was kept by the churches, wherefore the College found need to appoint committees on this subject and on that of disease and meteorology.

Their value ceased in after-times, the city having assumed charge of registration, and the county that of the weather, which Parke found troublesome, in 1792, because he could not buy a barometer in the city of Penn.

The history of an old and learned institution is that of its members and its relation to public affairs. No man can hope in the scope of an address to set before you the shining roll of the men who have illustrated our story with duty done simply and in private, of patient,

charitable lives, of those larger existences which left their mark also on the science of their day, and to this memorable hour have sustained in noble succession the prominence of this city in all that lifts our art and its sister sciences above the common levels of applied usefulness. The task were hopeless, and belongs to the historian rather than to the orator.

But our relation to the public cannot be thus readily disposed of. The acts of single men help to give us collective power to interfere in public matters, and here this College has been up to this day potently active. To it came early for advice in all affairs of health and quarantine the city, State, and general government; and the minutes amply record that it has labored conscientiously to aid the Commonwealth and the city as to sale and importation of pure drugs, as to parks, water-supply, education, drainage, and the many other problems which call for advice and direction from experts.

To the physician epidemics are his battle-fields. His daily life is hard enough, and, unlike the soldier, he lives amidst constant perils, of which habit has made him negligently forgetful. He is assisted to be unthoughtful as to risks by the fact that the community thinks little of those which are not, like the soldier's, occasional, or which it does not largely share. You must have lost sense of heroism if you do not feel some thrill of pride when you look back with me over those sad years in which the Fellows of this College, amidst the contagion of terror, faced the storms of death which from 1793 to 1804 swept over this city and forever ruined its mere commercial supremacy.

Let us see how well this College met it. Several of its Fellows could recall the epidemic of 1762—the Barbadoes Plague—the dreaded yellow fever. Rush, a student, made notes of it in his constant way, and Redman, an older man, described it with accurate skill. A few hundred died, and for thirty-one years the great town flourished undisturbed. For two years the College had at times been urgent as to quarantine, but selfish, short-sighted commerce had been more potent. On the 25th of August, 1793, a special meeting of the Fellows was called "to consider their duty because of the fever of alarming nature." Rush, Hutchinson, Say, and Wistar were to report on the 26th. Nothing, on the whole, could have been better than the calm good sense of the letter of public advice which the College, at the instance of their committee, addressed to the mayor, Mathew Clarkson, and to the people at large. At this meeting the President describes the fever of 1762. Tilton, our Associate, advises tents as hospitals, and the College decides to meet every Monday. How simple it all sounds, the quiet councils, the talk as to treatment! The Fellows assemble on the 3d, 6th, 10th, and 17th of September, and consider Alexander Hamilton's letter of inquiry as to the fever, and answer Warren, of Boston. Meanwhile the plague is on the people, and the College meets no more until November.

To speak of this awful summer is to speak of a population degraded by the very insanity of fear. The rich fled first, and at last almost all who could go. In round numbers Philadelphia had six thousand houses and forty-nine thousand souls. Some three thousand houses were closed. Twelve thousand persons fled to the country: Carey says seventeen thousand. Of those left behind, eleven thousand took the fever, and one-third of these died. Before this appalling death-rate all but a rare few gave way. In deserted streets, between rows of closed houses, where commerce had ceased, men walked down the middle of the causeways and declined to shake hands with friends, or turned aside from any who wore the badge of mourning. Thousands of both sexes smoked tobacco to avoid disease, or carried vinegar or camphor or bits of tarred rope for protection, while bonfires at night and firing of muskets to disperse contagion ceased only when the mayor forbade them. The churches were shut; most of the weekly papers ceased to appear. For the laborer there was no work. Starvation drove him to crime, and thieves lived riotously in deserted houses. At last family ties were broken, men fled from their dearest, whole families deserted the bed where the father lay dying, nurses were hardly to be had, and still the sombre death-cart went its nightly round with its negro driver, and in answer to the dreary cry, "Fetch out your dead," corpses were lowered from open windows on to the cart, backed up on to the sidewalk, or were carried out in haste to be put across the shaft of what was called a chair, and hurried away for swiftest burial. So lower and lower men sunk, as the plague increased, until at times the dead lay unburied, corpses were found in the streets, and the climax of misery, neglect, and profligate riot was reached at Bush Hill Hospital for the poor. Amidst this horror of disease, of selfishness, of crime, there were men who grew morally stronger through that which enfeebled the mass. The most of the physicians of the blighted town went about their duties untouched by panic, undisturbed by fear. In our own ranks were none who failed. Their names are to be read on every record of those dreary hours. Theirs was what Ruskin speaks of as "that constitutional serenity in danger, which, with the wise, whether soldier or physician, is the basis of the most fortunate action and swiftest decision of deliberate skill." (Preterita, p. 379.) How they differed as to treatment, and how doggedly they held their beliefs, concerns us little. That they did their full duty as honest gentlemen concerns us much.

Hutchinson died, and Morris and many others not in our fellowship. None altogether escaped untouched by the plague, which swept away ten physicians in a month. Says Rush, "At one time but three physicians were able to do duty outside of their own houses. From this cruel summer until 1806, no year left us free from the fever, but the worst of it fell upon us in 1798." Again the College had in vain sounded repeated warnings to the city, the State, and the general government. Again there is that eloquent blank in our minutes from August to November. It was more terrible than '93. Some forty thousand fled, and of those who stayed, about four thousand died, nearly half of those attacked, and again the scenes of '93 were repeated, and again, as in '93 and '97, our ranks were thinned, and only more did not die because nearly all were protected by previous disease.

There were physicians who fled from this more deadly horror, but in the thick of it I find the names of our Fellows. Griffitts's daily record, meant only for his own use, is before me as I write. He says, "My patients are mostly among the poor. While I went to the country to see my sick child, half a day, upward of fifty knocks at my door. Yet through all this I am favored with calmness. My lot seems cast among misery and death. A day of trouble. Buried a beloved servant. Much unwell to-day. Too much to visit. Thus they suffer from unavoidable neglect. I feel indeed alone."

We lost Hugh Hodge and Annan later of the same disease, and through all of these sad years we find always ready, always dutiful, the best of the men whose lives I have sketched. Scarce one escaped the wounds of disease, and at least six died; but none failed us. Surely this is a record to look back upon with that pride which nourisheth good example. We may grieve for suffering, and regret careers cut short, and yet desire to preserve their remembrance;

> "Nor could Humanity resign
> Each hour which bade her heart beat high,
> And blazoned duty's stainless shield,
> And set a star in honor's sky."

The horrors of 1825, with its smallpox, and the cholera of 1832, found the successors of these men as able, as simply ready, as courageous.

Meanwhile the battle as to contagion and importation, and bleeding, and emetics and calomel, raged with a fury of personalities for which it is difficult to account, but which the tenacity and irritability of Rush may in a measure explain. It caused Rush a bitter personal quarrel with Andrew Ross, and disputes between Rush and Kuhn as to the treatment of Hutchinson, and led to the resignation of Rush and the formation of the short-lived Academy of Medicine. These virulent intellectual duels ceased by degrees when the new dispute as to vaccination arose, and, as most of our Fellows favored it, it seems hard to explain their action. In December, 1802, Lettsom sends the College from London vaccine virus, and shortly after is elected an Associate, while, alas! Jenner, proposed by Plunket Glentworth, fails of election,—a sad commentary on the too conservative tendencies which nowadays have somewhat ceased to trouble us. But a little while and the world of opinion was with Jenner. Three or four years later no man would have dared to blackball one of the immortals. The moral is not far to seek, and time has not quite worn it too threadbare for use. In all our history we have little to feel ashamed of, and this reproach comes swiftly after—nay, among—the deeds which showed of what heroic stuff were the men whose portraits hang around our hall.

Our early years produced a few notable essays, but the great and active intellect of Rush was lost to us, and his influence kept out of our fellowship Physick and Mease and some others of note. As I look forward over our minutes up to 1820, the papers are fewer. In some years there is not one. Often there is no quorum, Currie writes, and tells us in a wandering and irritable letter that we are inert and useless, which is hardly true, for still in all public affairs the College is active and attentive. Death, too, has been busy with the men who had smiled in her face so often. Some twenty are gone,—the surgeon-soldiers of 1776, the veterans of '93 and '98. New names appear, though slowly. Sixteen are added before 1807, and of these the yellow fever has taken four. In several years no election of a Fellow occurs, and none from 1807 to 1810. In 1811 we gain the first I personally remember, the honored and well-loved Hewson, some time our President, then Chapman, of joyous and social fame, Neill, Parish, the Bartons, and Edwin Atlee. And now, in 1823, Currie, Parke, and Griffitts, alone, seem to be left of our institutors, but as to some others I can find no note. It is difficult to explain the intellectual inactivity of the College in these years. It was rather paresis than paralysis, inertness than want of power. But why did we survive at all? The Academy had perished; the Philadelphia Medical Lyceum had come and gone; the Philadelphia Medical Society, the Kappa Lambda, the Medical Association of Philadelphia, had been organized, and were soon to die out or had already disappeared.

We were saved, I fancy, by that which preserves the vitality of families,—great traditions which nourish pride, and the conservative power of property: careful treasurers had begun to hoard for us a little money, and our library, if as yet small, was valuable. Moreover, we were still, as always, the public advisers, and the position of adviser is one which flatters. Then came the fortunate accessions from 1824, and we win illustrative

force as we get Hartshorne, Bond, Hodge. Meigs, La Roche, John K. Mitchell, Darrach, and, notably, Wood and Bache, familiar collocation of names, and almost as one in friendship and usefulness; Pennock and Gerhard, Hays, Pancoast, Mütter, Carson, Dunglison, Norris, McClellan. Catalogues of names are valueless, but these are winged with memories. Thenceforward our meetings grow richer in interest, even if at times some lack of activity is still obvious. There is now too much work done for careful analysis here. Twice vain efforts are made to limit the Fellowship. A fee-bill is formed in 1824, and we find only twelve surgical operations enumerated. These multiply in later tables of charges, but one would be puzzled to make such a list to-day. At last we abolish the whole business, and leave men to act in this matter as seems best to them.

We have come now to the time when physicians yet alive and active began to be felt in our affairs. All those I have just named are dead. Let us turn anew to what we have done as a College, work in which all have helped, and which shows best the affectionate interest with which we have all regarded this institution.

We met first in Fifth Street. In 1791 we carried ourselves and our modest library—one case of books—to the Philosophical Society rooms, whence we journeyed to the Mercantile Library building, then on Fifth Street, and in 1854 to the little house on Spruce, within the Hospital grounds. As I first climbed its well-known stairs, in 1856, I remembered the picture, by West, of Christ healing the sick, which in my childhood hung on the wall. The debates used to be sharp in those days. There was Wood in the chair, most courteous of men, gently formal, and of ever-ready kindness to younger physicians; a peace-making presence when the too positive Condie was raging in debate, and Charles Meigs, with his poetic nature and talk of singular freshness, was spurred to sharp reply, and Hodge grew graver and yet more sedate, and Bache sat ready to drop with deliberate slowness of contradiction on the inaccurate. As I write, the visage of Gerhard returns to me, with its grim humor. A man quick of speech and as quick to regret, an unbalanced nature, but a keen and subtile observer. There is stout George Fox, and the slight, delicate figure of La Roche beside our great surgeon Pancoast, sturdy, earnest, and original, a curious physical contrast to his colleague Mütter, small, exquisitely neat in person, and courtly in manner.

You will forgive my gossip. I should like to believe that our juniors have reason to look up to us as we did to these men. A crown seemed as remote to me then as the chair which, by your grace, I now hold.

We owe our present home chiefly to the liberality of George B. Wood, to George Fox, and to the unceasing efforts of Isaac Hays, who, as chairman of our Building Committee, served the College with that high-minded sense of duty which he carried into every relation of life.

In 1856 our building fund, by careful nursing, had grown to sixteen thousand dollars. Our first large accession, like much else that is good, came from Wood. A Western quack had infringed the copyright of the Dispensatory, and the heavy damages awarded were generously given to our building fund. In the same year, by good fortune, Thomas Dent Mütter offered to give us his museum and to leave us an endowment of thirty thousand dollars, on condition that within five years we gave this collection a fire-proof shelter. Gift after gift from Dr. Wood followed,—not less than ten thousand dollars in all,—and in 1863 we moved to our present hall, to which we have but of late added the third story contemplated in the original plan.

The College museum at once grew into importance by the addition of Mütter's gift, and is now one of the most valuable and interesting collections in America.

The library, which owed its first gift and legacy of books to John Morgan, now numbers nearly thirty-eight thousand volumes and some twenty thousand pamphlets, and is second in America only to that which the ample purse of government and the genius of the greatest of medical bibliographers, John S. Billings, have created in Washington.

Its annual growth, some two thousand five hundred volumes, with thousands of pamphlets, is due to the constant supply of new books, and especially of journals, of which we receive at least three hundred and twenty-five. This steady inflow of weekly and monthly publications represents for us the swiftly-changing tides of knowledge, the floods and ebbs of opinion, the never-ending novelties, good or bad,—all to be put on trial. By-and-by the best of this matter, solvent in a hundred journals, crystallizes into more permanent shape in books. This vast accumulation and the multitudinous contributions it represents has, of course, its embarrassments, for not all new facts are valuable or correctly interpreted; but, be they true or not, we must at times have access to them all. Whilst in some very good ways our profession is unyieldingly conservative, as to matters of intellectual opinion and modes of practice it is, nowadays at least, alertly ready to accept the novel and as ready to give up the old.

Books are the best tools of our business, and a great library like ours insensibly educates by tempting men with the noblest of opportunities. It is like an unfailing friend to whom we go for counsel and helpful advice, and a catalogue is its ready memory of all that our greatest knew and taught. Look around that great collection in all tongues.

It is a vast presentation of the thoughts, the beliefs, the victories, the defeats, of that profession which has been, as compared to any other, the purest, the most single-minded, the most simply devoted to its moral creed, the world has seen through all its changeful ages. It has its peerage, its lords of thought, its sturdy, practical commons. Yet here is no set creed of dogmatic beliefs. We make and unmake our rulers, and time, which is more wise than Bacon, has a large vote in the matter; but while systems of medicine crumble, and doctrines have their little day, and men have been intellectually right or wrong, it is pleasant to remember that the lofty code of moral law our Greek Fathers taught has kept through all these productive centuries an invigorating control over the lives these gathered volumes represent. Thus, for him who loves his art, a great medical library is full of lessons in the conduct of life. There, side by side, the feeblest and the strongest meet. What a record of the follies and caprices of learning, of devotion, of martyrdom, of simple usefulness, of ambitious failures! Here are stately tomes unread for ages. Here is some little volume which has changed the great currents of thought and brought hope and relief to a thousand bedsides. In yonder corner is a modest book-case, which groups the bric-à-brac of the bibliographer, the mad jester, the cranks, the queer anecdotists, the priceless incunabula, the medical poems.

I like to think of the book-loving men to whom we owe this collection. Morgan, the scholarly; Hays, editor for fifty-three years of the best medical journal the world has seen; Moreton Stillé, too early dead, with his half-used store of varied learning; Wood, Betton, Mütter; Gross, the great surgeon; Hodge, the famous teacher of obstetrics; Lajus, that gentle and modest scholar, who once said to me, in his odd way, "I like the men who are like books, and that is why I like Samuel Lewis."

I have broken my rule for the first time, to name a living Fellow of the College, the constant benefactor of our library; but in proportion as a man is modest, self-forgetful, prone to avoid public recognition, one is tempted at a time like this to say what we think of him to whom we owe so much. Kindly friend, learned and liberal scholar, we are glad that you are here with us to know, once for all, how lovingly we thank you for the unstinted generosity of these many years.

In that last great war, we most of us so well recall,—in that vast struggle, whose authors we do well to forgive, but whose trials and lessons we do as well never to forget,—this College was true to its traditions.

There are on our list to-day at least one hundred and four men who served their country in the field, in hospitals, or at sea, in those years of sacrificial trial.

Whatever we may have thought or felt of that section of our race which faced us in fight, of this at least I find it a pleasure to feel sure, that wherever men were sick or wounded our ancient guild did well its Christ-like duty. As to that record, North and South, there can be neither doubt nor difference.

I close with satisfied pride these annals of the past and its dead. I see about me men whose books are in every tongue of Europe, whose works are known and honored among the learned of every land, men who wear by just decree of their fellows the unseen crowns of honorable estimate. I see, too, the young in work, the men who are to follow us. To them we shall soon consign this precious heritage, the record of a century of duty; a hundred years without one break in our meetings, save when pestilence thrust upon us a more imperative service. There is that in these years to make them proud of a fellowship which in war and in peace has left us examples of single-minded workers unknown to fame, of the charity without taint of selfishness, of heroic lives lost in battle with disease, of gentle scholars, of daring surgeons whose very fingers seemed to think, of physicians rich with every professional grace. The pride of lineage is valueless which does not secure to the future vitality of usefulness, and I must have told my story ill if to every physician who hears me its illustrations have not the invigorating force of moral tonics.

I turn now from the present and face the silence of futurity. As earnestly as our first President, I pray with him that all those who sit around me, and all who are to come, do publicly and privately serve their generation.

Feeling, like him, the weight and dignity of my office, and to-day more than ever, I look onward thoughtfully to that next centennial time. Every heart that beats in this hall to-day will have ceased to pulsate. Another will stand in my place. Reviewing our works and lives, he will be able, I trust, to say as confidently of us as I have said of your fathers, These too belonged by right of dutiful lives and sincere work to our great, undying brotherhood.

OFFICERS OF THE COLLEGE OF PHYSICIANS.—At the annual meeting, held January 5, the following officers of the College of Physicians of Philadelphia for the year 1887 were elected:

President.—Dr. S. Weir Mitchell.

Vice-President.—Dr. John H. Packard.

Secretary.—Dr. Isaac Norris.

Treasurer.—Dr. Charles Stewart Wurts.

Honorary Librarian.—Dr. James H. Hutchinson.

Recorder.—Dr. J. Ewing Mears.

Censors.—Drs. Lewis Rodman, William Goodell, Alfred Stillé, and Samuel Lewis.

Councillors.—Drs. Morris J. Lewis and James Tyson.

Dr. George E. De Schweinitz was elected for Fellowship.

ORIGINAL COMMUNICATIONS.

TWO CASES OF UNSUSPECTED FRACTURE OF THE SKULL.

BY HARRY FRIEDENWALD, A.B., M.D.,

Assistant Resident Surgeon, City Hospital, Baltimore, Maryland.

PATIENTS with head-injuries present phenomena of every grade of diagnostic probability, from those with such positive symptoms as to lead the surgeon to the exact nature and locality of the cerebral lesions to those with symptoms that are so trivial or misleading as to divert attention from the real injury and cause erroneous diagnosis, as, for instance, that of intoxication in a patient really suffering with serious skull-injury. It is the gravity of the error in these which leads me to report two illustrative cases which were admitted into this hospital during the last year, with the view of calling especial attention to the misleading nature of the symptoms.

Case I.—C. H., a laborer, aged 41 years, was admitted on May 12, 1886, into the hospital. The statement was then made that he had fallen, about an hour before, from a height of seven feet, striking his back over a block of wood. His condition when admitted was good; pulse and temperature were normal; the skin was nowhere broken, and no spots of extravasation of blood were found, excepting some ecchymosis of the right eyelids; the pupils were normal. He complained chiefly of pain in the back and headache, and vomited several times. During the following night he continued to vomit, and also during the next forenoon, and he still complained of headache. The headache decreased gradually under the influence of bromides.

May 15. Patient was out of bed, walking about, and improved.

May 17. He walked about during the day, but his mind wandered; towards evening he grew worse; his gait became tottering; made ropes of his bed-clothes and talked to himself of making fast to some object. Up to this time he had been rational; he had told us how the accident happened, and answered all other questions put to him.

May 18. During the morning he continued his work with the bed-clothes. Later, when spoken to, he would recognize the speaker, but he would soon relapse and mutter to himself.

May 19. Breathing became rapid, obstructed, and difficult; delirium became more marked.

May 20. Breathing very difficult and rapid; frothy mucus in nostrils and mouth. In the forenoon (about 10 A.M.) he walked out of the ward into the street. His tottering gait continued since first noticed. He recognized friends in the afternoon; late in the evening he became unconscious. Respiration steadily grew more labored.

Patient died at 1.30 A.M., May 21.

The post-mortem examination, made by Dr. N. G. Keirle, showed the lungs deeply congested; in the heart was found a very firm "chicken-fat" clot in right auricle and ventricle, extending into pulmonary artery; kidneys slightly enlarged from congestion. But more important and surprising were the results of the examination of the head: here were found extensive fractures, hemorrhage, and inflammation. A piece of the thin upper wall of the right orbit at the outer part was entirely broken loose and separated from the remaining frontal bone; there were no linear fractures connected with this. A linear fracture beginning at the left jugular foramen ran across the occipital fossa and the crest of the occipital bone, through the right occipital fossa and the petrous portion of the right temporal bone (behind the internal ear), and ended at the foramen spinosum. The occipital fossa contained about two ounces of sanious pus. In the right occipital fossa there was a blood-clot about two centimetres by five millimetres. Beneath the dura mater over the right orbit there was another clot three centimetres in diameter.

Certain features of this case make it very interesting. In the first place, the primary cause of death—the fracture of the base of the skull—was not recognized during life. The only symptoms immediately due to the fracture, the headache and the ecchymosis of the eyelids, were so uncertain, in the absence of positive signs, that a diagnosis of fracture would have been a mere guess. The headache and the vomiting were ascribed (perhaps properly?) to cerebral concussion, and the general ecchymosis of both eyelids and of the right eye was regarded as trivial,—a slight bruise possibly caused by striking some projection amid the lumber into which he had fallen. Not the lack of positive signs alone, but his general condition and the symptoms presented, as well as the short distance of the fall, were apparently deserving of so little consideration as still more to divert the view from the real injury and direct it to the slight cerebral concussion and the unimportant bruise of the back. The consecutive intense pulmonary congestion was easily mistaken for a developing (and independent) pneumonia (which disease was very prevalent at the time), and the delirium was ascribed to it.

Case II.—A. C., aged about 30, was brought to the hospital about noon of December 11, 1886, by the police. They had picked him up on the street a few minutes before, believing him to be drunk; but, as he would not answer any questions, they took the precaution to bring him to the hospital for examination. It was found that he walked with staggering gait; that he would not answer any questions put to him; and that he had the odor of whiskey about him. His pulse was weak, and his hands and feet cold, and it was therefore thought best to put him to bed and let him rest and warm up. He remained quiet and undisturbed until the evening. On examination at 6.30 P.M., his pulse was strong and beat 96 per minute; his respirations were 25 per minute, and of the Cheyne-Stokes character; his temperature was found to be 103.7° F. He would constantly repeat a few phrases, and was very restless. When disturbed, he would ward off those offending him by regular and apparently voluntary movements of the arms. He would forcibly close his eyelids when the attempt was made to open them. The pupils were slightly contracted, the right one being the smaller. His reflexes were increased; tickling the soles of his feet would cause violent movements in both legs. There was no anæsthesia or paralysis. When uncovered, he would attempt to bring the cover up to his neck and keep it there. His thighs were kept flexed on the abdomen, the legs flexed on the thighs, the hands held over the scrotum. Upon very close examination of the scalp, a narrow, transverse scar was found on the back, about one and a half inches long, and apparently very superficial, covered with a thin, dry scab. His condition remained stationary during the night.

At 9 A.M. on the following day the pulse and temperature were the same as the previous evening. The left leg and arm appeared rigid. The right leg was unchanged. The respiration partook still of the Cheyne-Stokes type. Opisthotonic contraction came on after he had been disturbed. At 1 P.M. his breathing became stertorous, the pupils began to dilate, the temperature rose to 105°. He died at 5 P.M. the same day.

The treatment consisted in this case in applying an ice-bag to the head, cold sponging, purgation by one drop of croton oil, and hypodermic injection of antipyrine.

The post-mortem examination, made by Dr. Keirle, revealed a diffuse effusion of blood in the subaponeurotic and periosteal tissues in the region under the wound of the scalp mentioned above. A linear fracture was found beginning here,—at the median line, just below the apex of the occipital bone,—running to the left into the lambdoid suture, separating it; then up the squamous suture 2.5 cm.; then, curving downward, through the squamous portion of the temporal bone. It then diverged, one limb continuing downward and going to the temporal end of the zygoma, the other crossing the temporal fossa horizontally for the distance of 4 cm. Extending through the left inferior occipital fossa was another linear fracture, beginning at the main fracture, 2 cm. to the left of median line, and 1.5 cm. below lambdoid suture, and running diagonally downward and outward towards the jugular fossa. There was a blood-clot outside the dura mater, 5 cm. by 8 cm., and 1 cm. deep, resulting from laceration of the posterior meningeal artery. There was also intrameningeal hemorrhage in the left middle fossa, and in both posterior fossæ. The left temporo-sphenoidal lobe near the apex was considerably disintegrated. The lungs were found congested.

From this brief account it will be seen that a very extensive fracture at the base of the skull may present symptoms either so few or so unimportant as to obscure the injury entirely. There was not a symptom present when the patient was first admitted which we do not see daily in intoxicated persons who have been exposed. It is probably true that he had a fall; but then it must not be forgotten that no history of the patient could be obtained. It was evident when the symptoms of active brain-disorder appeared that some serious disease was in progress; but none were present which pointed to fracture.

CITY HOSPITAL, BALTIMORE, December 20, 1886.

A SUGGESTION FOR REDUCING DISLOCATIONS OF THE FINGERS.

BY J. W. MACFARLANE, M.D.,

Demonstrator of Surgery in the Western Pennsylvania Medical College.

WHILE demonstrating to a class on minor surgery the appliances used to reduce dislocations of the fingers, some difficulty was experienced in keeping Levis's instrument in position, even with a wet bandage applied to the part.

Having of late been obliged to wear some of the gum finger-stalls of the shops, to avoid poisoning in a cut, and recognizing how they adhered when once in position, the idea suggested itself that one of these would be an excellent covering for the finger, over which Levis's instrument or a clove-hitch could be secured if desired.

A close-fitting gum finger-stall was then applied, and, upon grasping with the right hand the finger so covered, we found that

we had such a power and perfect control that further appliances were unnecessary,—slipping being out of the question with a finger so covered, especially if the operator's hand is warm.

This simple suggestion may perhaps not have the merit of originality, although I have never come across it before; but it seems to me that much more accurate and judicious traction can be made when the dislocated finger is in the firm grasp of the fingers of the right hand, while the thumb of the right and the whole of the left hand are free to manipulate with, than in the customary method of procedure. Or, if desired, the gum finger-stall can be used as a fixation-point for Levis's instrument or the application of a clove-hitch.

3617 Butler Street, Pittsburg.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF J. M. DA COSTA, M.D., LL.D.

ACUTE CEREBRO-SPINAL MENINGITIS DUE TO CHRONIC SUPPURATIVE OTITIS.

GENTLEMEN,—I shall first call your attention to some specimens taken from a case which died recently in the Men's Medical Ward, and of which I will give you a brief history.

The patient from whom these specimens were obtained was brought into the hospital in a condition which prevented us from getting from him very accurate information with regard to the history of the case; nevertheless we succeeded in learning, partly from him and partly from his visitors, that he had had an attack of typhoid fever during the past year, from which he made a good recovery; he had obtained employment as a waiter since, and had been well up to the attack for which he was admitted. His recovery from typhoid fever therefore was complete, and he was able to attend to his occupation after it. We have also ascertained, what we did not know at the time, but which I will mention here in giving you the history, that he had had a severe earache, with inflammation of the left ear, which had got well after a discharge of pus from the external meatus, about a year previous to his coming here. Whether this occurred prior to the attack of typhoid fever or afterwards I cannot at present say, though I think it probable that it was before.

Please note that he was well, and attending to his usual occupation, when his last illness began. On the 13th of this month, being, as he thought, in perfect health, he was taken with pain in the head so severe that he was obliged to go to bed. There is no history of an actual chill, and no mention of gastric disorder. His headache persisted, and on the 16th it was noticed that he had lost the power of speech. He had to be helped to the hospital, for he was quite weak, though still able to walk some; his mind was fairly clear; he attempted to speak in reply to our questions, but could not articulate distinctly; he also tried to write, but failed, more from weakness probably than from inability to direct the pen; his headache was still very severe, especially about the left temple and ear, with great restlessness. There was stiffness of the muscles in the upper portion of the neck; the facial muscles were not involved. The tongue was dryish, brown, and slightly coated, protruded with difficulty; no sordes upon his teeth or lips; both pupils were dilated, but responded equally to light; temperature was 102°, the pulse was 86, and the respirations 20 in the minute; the heart and lungs, upon examination, showed nothing abnormal. The stiffness of the muscles at the back of the neck attracted our attention particularly. It was also noted that he had very marked photophobia. No eruption could be perceived on any portion of his body.

Now, gentlemen, subsequent to his admission the temperature-record was sometimes high, sometimes low. The chart shows it at 105.5° at night, and then 100°; on the 19th it was 104°, and on the same evening it was 99.8°; on the 20th it goes up to 102.2°, and then down to 100.4°. In other words, after the first few days of high temperature there are great variations, and then a temperature which does not again go above 102.4°, but remains at about 99° to 101°. The pulse-record also gives evidence of considerable irregularity: in the main, however, the pulse is a slow pulse, notwithstanding the elevated temperature. I find it recorded at 86 and 89, and only once at 100, and in the last ten days it was among the seventies.

There was no vomiting; the headache continued severe; if he complained less during the last few days it was probably because his intelligence became dull, and he had less ability to express his sensa-

tions. The pupils became contracted and sluggish, and he gradually sank into a comatose condition, in which he died. Still, until shortly before death he seemed to be doing well, and the change for the worse was a rapid one. I did not look upon the case as hopeless until twenty-four hours before death occurred.

I will merely say in reference to the treatment that the scalp was leeched with evident advantage. Swedish leeches were applied behind the ear until eight or ten ounces of blood were taken, and the bowels were freely moved by purgatives. Ice was applied to the vertex, and he was given bromide of potassium in large doses. Early in the treatment, in order to relieve his pain he had repeated doses of opium, which afforded him decided relief from his sufferings.

I will now show you the specimens and then discuss them: they are very instructive. It is not often that you will see a case so well marked as this of suppurative meningitis. You perceive that there is over the whole of one side of the brain, the left, also at the base and extending towards the front, a white layer of exudation under the dura mater; the left hemisphere is, in fact, nearly covered with pus, though chiefly on the middle and posterior lobes and between the arachnoid and dura mater. There are evidences also of meningitis spreading from these to the surrounding parts. Upon section the brain itself seems more vascular than usual, but our pathologist, Dr. Longstreth, who has examined it carefully, says that it is not abnormal. It is, therefore, a case in which there is extensive meningitis, especially upon the left side of the brain.

Now, gentlemen, that this was a case of meningitis, with exudation, the inflammation extending down to the spinal cord, is demonstrated by the autopsy. It proved it to be what we suspected during life, a case of cerebro-spinal meningitis: looking upon this term in its pathological sense, the lesions confirm this. But there is another point to which I wish to call your attention. It was important to decide whether or not it was a case of cerebro-spinal meningitis associated with and caused by cerebro-spinal fever,—one of those sporadic cases which linger after an epidemic, of which we had the threatenings last spring. He had, when admitted, all the symptoms of the specific fever except one, that is the eruption. On looking back upon the history of the case, there was one other symptom which I afterwards noticed: it was an absence of extreme hyperæsthesia, which is so marked in the specific fever. Barring these, it had the features of an ordinary case of cerebro-spinal fever. Now, the question comes up, Was it really a case of cerebro-spinal fever? These are the usual lesions which we find. Why do I hesitate to class it with such cases? Is there any other solution which might be offered? Yes; we found one which was afterwards confirmed by the autopsy. There was long-standing disease of the middle and internal ear, the temporal bone was softened and in places broken down, and the inflammation had evidently spread from this diseased bone to the dura mater. We have reason, then, to believe that this typical case of cerebro-spinal meningitis was not an instance of the specific disease, but one in which there was a secondary morbid process due to extension of inflammation from the ear,—an acute disorder the result of a chronic malady. This is not a case of abscess of the brain directly due to diseased bone, which is not uncommon as a sequel of chronic otitis, but it is one of the rarer forms, in which the inflammation travels along the lymph-spaces by continuity of structure and carries the septic infection to the convexity of the hemisphere.

I will call your attention to another interesting point, and one that adds to the difficulty in making up your diagnosis in a case of cerebro-spinal meningitis,—the suddenness of the onset. Occurring as an unusual complication here, it is the rule in cerebro-spinal fever. Yet a case like the one under discussion may arise suddenly and the symptoms set in abruptly. A correct conclusion will then largely depend upon the history. I observe, therefore, that we find cases arising suddenly —like this one in a man in apparently perfect health—which would lead you to suspect cerebro-spinal fever, and yet the whole thing may be primarily due to ear-disorder.

This is an instructive case, and may serve as a warning against accepting the most obvious explanation as the true diagnosis. The suddenness of the appearance of the symptoms is an important point to bear in mind in connection

with the history of previous ear-disease. You may ask, Does my experience furnish a parallel case? Yes, I can recall several. I am reminded of the case of a young married lady who also had had attacks of vertigo, and about a year before had had a discharge of pus from the ear, but which had passed away and was almost forgotten. While in perfect health apparently, she was taken suddenly with violent headache and the usual symptoms of meningitis. She rapidly became comatose and died, and the autopsy showed a similar state of things to that which we have just been discussing: a person in perfect health passing at once into violent meningitis. In our case a diagnosis was not impossible, for during the illness a discharge from the ear took place. I call your attention pointedly to the circumstances of the case, because attacks of meningitis coming on during perfect health are apt to be misleading unless you are aware of their possible connection with latent ear-disease.

There are other points of which I might speak. One is the irregularity of the temperature, and another is the slowness of the pulse. This is especially interesting, because you have here reproduced what is the rule in the specific form occurring in epidemics. Irregularity of temperature and slow and irregular pulse we often find in typical illustrations of cerebro-spinal fever. This brings up for discussion the interesting question, Is not this peculiar temperature and pulse due more to the local inflammation of the brain than to the blood dyscrasia, to which it has been generally attributed?

I have mentioned briefly several points of interest in the treatment: that local depletion by leeches gave some relief; that opium proved its usefulness; and that the pupils became more contracted under its use; but, since you did not see him during life, I will not further extend these remarks. I will, however, in conclusion, answer a question which must be in your minds. I spoke of the absence of eruption, and you wish to ask, Would not the absence of eruption settle the diagnosis between the case of meningitis due to the poison of cerebro-spinal fever and that due to other causes? I answer, Not always: because in some cases occurring in the course of an epidemic, where the specific cerebro-spinal fever is undoubtedly present, the eruption is conspicuously absent.

TRANSLATIONS.

RESEARCHES RESPECTING THE AXIAL NERVOUS CURRENT.—At a recent meeting of the Académie des Sciences, M. Marey read a physiological communication from M. Mendelssohn, who had proved that the electro-motor power of the axial current of a nerve-fragment increases with the length of that fragment, though not proportionally with it. If the trunk of the nerve be gradually shortened, it is seen that the direction of the axial current ceases after a certain limit to conform to the rule which the author had already mentioned, —viz., that the direction of the axial nervous current is always in opposition to the direction or course of the physiological function of the nerve. The electro-motor power of the axial current increases with the area of the transverse section of the nerve. This correlation disappears when two different nerves are compared in the same animal or analogous nerves belonging to animals of different species. The electro-motor force of the axial current decreases with the exhaustion of the nerve which is induced by prolonged tetanization. This exhaustion may even completely destroy the axial current. Desiccation of the nerve, and especially of its sectional surface, rapidly lowers the electro-motor force of the axial current. All these facts show that this current possesses essentially the same physical and physiological properties that M. Dubois-Reymond has described as existing in other nervous currents.

INFLUENCE OF SALTS AND ACIDS UPON FISH.—At a recent meeting of the Paris Biological Society, M. Richet communicated the results of experiments he had made in order to study the influence of different salts and acids upon water containing fish. Salt-water fish were taken for these experiments. The chloride is the most innocuous of all the salts of sodium. The proportion of this salt contained in sea-water is ten grammes to a litre. Sixteen more grammes to a litre would be required to cause death in a fish within forty-eight hours; whereas only five grammes of nitrate or one gramme of bromine would suffice. M. Richet made similar experiments with acids, which rapidly produced fatal results, even in weak solutions.

MEDICAL TIMES.

PHILADELPHIA, JANUARY 8, 1887.

EDITORIAL.

THE COLLEGE OF PHYSICIANS.

THE great medical event of the week has been the celebration of the Centennial Anniversary of the College of Physicians of this city. If any doubt existed as to the social status of the profession in Philadelphia, it surely must have been dispelled in the mind of any one who was present at the delivery of the address by the President at Association Hall,—a dignified and appropriate discourse,—or who witnessed the brilliant assemblage at the College immediately following it. The proceedings at the special meeting of the College were impressive, and the Reminiscences of Professor Stillé very judiciously supplemented those of the President. The graceful words of Professor Da Costa to the newly-elected Associate Fellows must have made them certain of their welcome, but no lingering doubt could remain after participating in the magnificent dinner of the College given in the Assembly hall of the Union League, which appropriately concluded the exercises.

There are few who are aware what an important part the College of Physicians has filled in the medical history of Philadelphia, which was so ably reviewed in Professor Stillé's address. Not the least of its services is that it has consistently labored to elevate professional tone; and in pursuance of this it, in 1843, framed a Code of Ethics which a few years later was substantially adopted by the American Medical Association. In 1848 it encouraged and aided the formation of the Medical Society of the State of Pennsylvania. In 1856 it took an active part in converting the Board of Health of this city from a merely political machine into an organization which has ever since been leavened by a quota of active and intelligent physicians. It has constantly instructed the public upon sanitary questions, and has repeatedly memorialized the Legislature for laws governing the inspection of drugs and medicines, for recording vital statistics, and other matters important to the citizens of Philadelphia. It has established one of the most valuable collections of works on medicine in the country, and given its use (with very slight restrictions) to the whole profession. By the publication of its annual volume of Transactions, it has served to stimulate and excite emulation among other medical societies which have sprung up under its ægis. May it continue its beneficent work for another century, and may those who continue its career remain faithful to its traditions!

PAROXYSMAL HÆMOGLOBINURIA.

THE separation clinically of hæmoglobinuria from conditions resembling it by the discovery of Harley, in 1868, that hæmoglobinæmia was its invariable precedent (the coloring-matter of the blood being merely excreted by the kidneys) has given to this class of cases special medical interest. Paroxysmal hæmoglobinuria, however, is to be distinguished from the toxic form, due to the ingestion of edible fungi (Morchella esculenta), the inhalation of arseniuretted hydrogen, the inunction of pyrogallic acid or naphthol, and certain chemical agents like potassium chlorate, glycerin, and some aniline derivatives, which exercise a destructive action upon the red blood-corpuscle. Severe burns of the surface of the body and the transfusion of alien blood have also been observed to give rise to hæmoglobinuria. The paroxysmal form, therefore, as distinguished

from that which is developed by the direct action of these special causes, may be regarded as a well-defined disease occurring in persons who apparently have some special predisposition to it.

In a communication to the *Nordiskt Medicinskt Arkiv* (B. xviii., No. 22, 1886), Professor R. Bruzelius, of Stockholm, gives the histories of three cases of paroxysmal hæmoglobinuria which had been for a long time under observation, and which were seen at intervals widely separated. These are all which have been reported thus far in Sweden, and in his extended experience the author had not encountered any others. Since only two cases have been published as occurring in Norway, it appears that the disease must be quite rare in these countries. Lichtheim stated that in Germany only two authentic cases had been published previous to the appearance of his treatise on this subject; since then, however, several other cases have been reported, showing that it is not so rare in the latter country as had been believed. Cases have been reported in much larger number in England, and a few have been met with in France and Italy. It appears in both sexes, and there is no restriction as to age: it has been observed at two years of age as well as at seventy.

The first of Dr. Bruzelius's cases was a woman, 27 years of age, who after remaining for a short time in a cold place had a chill, with elevation of temperature, urticaria, slight icterus, and hæmoglobinuria. Microscopic examination of the urine did not reveal any corpuscles, either whole or in fragments; spectroscopic and chemical examination showed the presence of hæmoglobin. The other two cases were men, aged 52 and 71 respectively.

From a consideration of these cases M. Bruzelius concludes that everything tends to prove that it is a disease of the blood, the destruction of the red blood-corpuscles taking place in the organs of the circulation, and not only in the kidneys, as Rosenbach believed. Refrigeration of the body is the most direct and frequent cause, according to Bruzelius, but other observers have also noticed hæmoglobinuria following prolonged muscular exercise and fatigue. Murri and Schumacher regard syphilis as the veritable cause of this disorder; of the three cases referred to only one had chancre, the others declared themselves free from infection.

In America it has been met with in cases of malarial poisoning, and, as pointed out by Dr. F. P. Henry, it is at least interesting to note that the early cases of this peculiar affection were relieved by the use of quinine.

THE MORBID ANATOMY OF EPILEPSY.

INVESTIGATIONS which throw light upon the morbid anatomy of epilepsy always attract special attention. A very interesting pathological study has been recently made by M. Zohrab* of a number of epileptic brains, in all of which necrosed, softened spots existed beneath or around the occipital or posterior horns of the lateral ventricles. Two of the autopsies were upon women who had had essential epilepsy, and two upon men who had presented epileptiform crises in the course of a cerebral lesion. His conclusions were (1) that there are a certain number of cases of epilepsy, either essential or secondary, accompanied by a softening of the region beneath the posterior horns of the lateral ventricles; (2) that in these cases the clonic convulsions are proportionate to the extent of the lesion, and are always more marked on the side of the body opposite to the cerebral hemisphere especially affected; (3) that the pathogenic influence of this lesion is still obscure, but that it is allowable to suppose the existence in this portion of the

* Archives de Neurologie for May, 1886.

white matter of an epileptogenic zone which it will be the office of experience to demonstrate.

NOTES FROM SPECIAL CORRESPONDENTS.

BALTIMORE.

THE profession of this city suffered a severe loss recently in the death of Dr. A. F. Erich, Professor of Gynæcology in the College of Physicians and Surgeons. Dr. Erich was only forty-nine years old, and apparently in perfect health, when he was suddenly seized, on the 6th ultimo, with pronounced symptoms of cerebral hemorrhage, which resulted in his death within twelve hours. He was well known for his improvements of gynæcological instruments and operative procedures. Among the former may be mentioned a self-retaining modification of Sims's speculum, various pessaries, a device for fastening deep perineal sutures, and a constrictor for rendering the cervix uteri bloodless in operations upon this organ. He also modified the operation for rupture of the perineum.

Dr. Erich was a successful and popular practitioner, a forcible teacher, and conscientious in all the relations of life.

A genuine sensation has been caused here by the discovery that the crime of "Burking" had been committed by three negroes, one of whom was an attendant in the dissecting-rooms of the University of Maryland. The corpse of a white woman was brought to the dissecting-room while still warm, and on examination was found to bear marks of violence upon it. Notwithstanding this, the body was prepared for anatomical purposes; but when the demonstrator of anatomy was informed of the suspicious circumstances connected with the reception of the body he notified the authorities, and an investigation resulted in the ghastly discovery that the woman had been murdered for the sake of the money that could be obtained by the sale of the corpse to the college. The police were promptly on the track of the murderers, who are now in jail awaiting trial. Two of them have already confessed their complicity in the foul work, and have implicated the third as an accessary before the fact.

The efforts to obtain some sort of regulation of medical practice in this State, to which reference has several times been made in this correspondence, have again ended in smoke. A committee has for several months past tried to induce the Medical and Chirurgical Faculty of Maryland to assert its ancient rights and privileges of subjecting all those desiring to practise medicine in the State to an examination, in default of a diploma from a respectable medical institution. But, for reasons previously pointed out, the Faculty declined to take any action, beyond submitting the question of its rights and duties to the Attorney-General of the State for an opinion. This official, taking his cue from the dilatoriness of the Faculty itself, declined to express an opinion. This leaves the entire matter *in statu quo*, with the probability that nothing will be accomplished in this direction until the profession takes the business out of the hands of the State Faculty and demands of the Legislature protection for the public against the shameless quacks, both in and out of the profession, who now infest this city and State.

The pathological laboratory of Johns Hopkins University has made a very successful beginning. About twenty physicians are now at work in the laboratory under the direction of Professors Welch and Councilman. Special researches are also being pursued by Dr. W. S. Halstead, of New York, and Dr. W. D. Booker, of this city. Dr. G. M. Sternberg, Surgeon U.S. Army and President and Chairman of the Committee on Disinfectants of the American Public Health Association, is making a thorough investigation into the practical disinfection of the dejections of typhoid fever, and of pure cultures of the typhoid-bacillus. In this work he is assisted by Dr. Meade Bolton, a former student in Koch's laboratory. The results already obtained promise to be of very great practical value.

G. H. R.

PROCEEDINGS OF SOCIETIES.

CENTENNIAL CELEBRATION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE formal celebration of the one hundredth anniversary of the institution of the College of Physicians, organized January 2, 1787, was held during the past week. The first ceremony was a commemorative address (see page 237) by the President of the College, S. Weir Mitchell, M.D., LL.D., which was delivered at Association Hall, at 7.30 P.M., on the 3d instant. It was followed by a reception at the hall of the College, Thirteenth and Locust Streets, which had never before held such a brilliant assemblage.

On the following day a special meeting of the College was held at noon. Professor Alfred Stillé, M.D., LL.D., delivered an address on "Reminiscences of the College," in which the speaker gave an historical sketch of the development and progress of the College and its magnificent library (now containing 38,160 volumes, besides 16,026 pamphlets), which has more than trebled in size in less than twenty years, and in this country is second only to the library of the Surgeon-General's Office in Washington.

The orator concluded his very interesting address in the following words: "In this partial retrospect of the history of the College during the last forty years, one can hardly fail to note that in it, as in political and social, and, indeed, every history, progress has depended upon individuals. The hour must come, and the man must arise who, by his voice or his example, stimulates other men to vigorous and fruitful action. As in its infancy the great name of Rush dominated the College, through his inventive genius and foresight, so in its later history George Bacon Wood ruled it by his wisdom and liberality; another has made illustrious his living name by opening a rich mine of intellectual wealth for all seekers after knowledge; and still another is distinguished for his liberality in promoting the social, artistic, and literary tastes of his fellow-members. All, by their example, have so warmed the enthusiasm and quickened the sympathies of the Fellows, that this commodious building, this precious scientific museum, and this noble library have sprung into existence in the brief space of a single generation.

"Let us hope that so fair a flower of science shall not languish through indifference, neglect, or indirection, and that at the end of another century our posterity shall be able to speak of us with unstinted praise, and with as sincere gratitude as we now feel towards those who prepared the way for this goodly habitation and temple dedicated to the service of humanity."

At the conclusion of the address the President announced the newly-elected Associate Fellows: Henry P. Bowditch, M.D., of Boston, Mass.; John C. Reeve, M.D., of Dayton, Ohio; David W. Cheever, M.D., of Boston, Mass.; Nicholas Senn, M.D., of Milwaukee, Wis.; William H. Draper, M.D., of New York; George C. Shattuck, of Boston, Mass.; R. Palmer Howard, of Montreal, Canada; T. Gaillard Thomas, M.D., of New York; Hunter McGuire, M.D., of Richmond, Va.; James T. Whittaker, M.D., of Cincinnati, Ohio; David W. Yandell, M.D., of Louisville, Ky.

After the ceremony of introduction was over, Professor J M. Da Costa, M.D., LL.D., delivered a brief address of welcome, as follows:

Associate Fellows of the College of Physicians:

Mr. President: Fellows of the College:

To me has been assigned the agreeable duty, on an occasion so interesting, of welcoming, on behalf of the College, eleven masters of our art as Associate Fellows. Our institution has put on its holiday dress to celebrate the day, the one hundredth anniversary of its existence, and one of the most pleasing features of the commemorative gathering is the admission of a number of men of distinction as Associates. In this the College is but carrying out the implied wish of its incorporators. It is calling those to it who have assisted "in the prosecution and advancement of useful knowledge for the benefit of their country and of mankind."

What thoughts would have filled the minds of those worthies who founded this College, could they be with us now! What rejoicing at the success of their literary and scientific undertaking would these old physicians of Philadelphia have indulged in! What pride would they, patriots formed in the stern school of sacrifice and suffering of a long war, have taken in the fact that from so many parts of their country, grown in these hundred years from sparsely-inhabited stretches of land into a teeming, powerful empire,—from cities they were familiar with, but in whose present magnificent proportions they would find themselves wondering strangers,—from wildernesses they scarcely knew of even by name, now thriving, populous States,—had come with a promptitude and rapidity which progress in applied science has alone made possible, those *viri docti et medicinæ periti* they would themselves have delighted in welcoming.

Every age has its impress and its tendencies. The queue, the knee-breeches, the gold-headed cane, the stately manner, the reverence for old wisdom, the classical canon, were their emblems, and bespoke that which they declared to be one of the objects of this College,—"to cultivate order and uniformity in the practice of physic." Though not blind to your other qualities, it would have been for any near approach to their standard of order and learning that they would have mainly esteemed you.

Our age is an age of zealous investigation and active change. Newly-elected Associate Fellows, we find represented in your ranks what in these days we chiefly honor in our many-sided profession. We find learning and order, but we also find love of research, originality, boldness; we note you quick of eye, fertile of resource, independent of thought. And if we have singled you out on this occasion, it is because you are the type we delight in, the true children of our time and tendencies.

How will it be when another hundred years have passed? Will the best traits that have made our investigators eminent go to form the cast of a medical mind reaching out into now unseen worlds of science, and looking, with eyes keen with suggestive research, at every line on every page that age has seasoned? Or will all knowledge be so plain and elementary that its application alone will be cared for, and investigation be regarded as nearly complete? It is not likely. The stone thrown into the water gives rise to ever-increasing rings; and so must it be with pursuits in Nature. There is still a greater world beyond the microscope and the telescope than we know with it.

Associates, in joining you to us to-day, we

bestow on you all this College has to bestow. It gives you full share in all that a century of learning, of culture, of pure aims, of renown, of high tone, most zealously guarded, has done to make it famed and respected. On its part, it takes a mortgage on your past acquisitions, as well as lays claim to a portion of the results of your future work: and when some fresh, thoughtful deduction in practical medicine becomes the theme of every pen; some new, life-saving operation is everywhere discussed; some clear monograph of exhaustive research and wide grasp is by every one lauded; some ingenious application of physiological experimentation is laid before the world; when we hear of a celebrated treatise of a great practical master being translated into yet more tongues,—we shall feel the pride of possession in our Associate Fellow, and, rejoicing in his success, claim him for the College as among our own. These are the feelings we have towards you, and we now greet and welcome you as sons of this old Institution with all the love of brotherly affection.

At the close of the exercises luncheon was served.

The concluding feature of the celebration was a dinner of one hundred and thirty covers at the Union League on the evening of January 5, at which the following distinguished visitors were present: George C. Shattuck, M.D., of Boston; T. Gaillard Thomas, M.D., of New York; Hunter McGuire, M.D., of Richmond; R. Palmer Howard, M.D., of Montreal; William H. Draper, M.D., of New York; Fordyce Barker, M.D., of New York; A. M. Pollock, M.D., of Pittsburg; Traill Green, M.D., of Easton, Pennsylvania; J. S. Billings, M.D., U.S.A., of Washington, D.C.; Henry P. Bowditch, M.D., of Boston; J. T. Whittaker, M.D., of Cincinnati, Ohio; J. C. Cameron, M.D., of Montreal; George B. Shattuck, M.D., of Boston; Nicholas Senn, M.D., of Milwaukee, Wisconsin; R. S. Ives, M.D., of New Haven; James T. Chadwick, M.D., of Boston; David W. Cheever, M.D., of Boston; E. Darwin Hudson, M.D., of New York; B. A. Watson, M.D., of Jersey City; W. W. Phillips, M.D., of Trenton, and others.

The ceremony of passing the Loving Cup was then observed with due solemnity.

While the Loving Cup was making its round the President announced the following toast: "The Founders of the College," which was drunk standing and in silence.

Dr. Henry Hartshorne delivered a brief address in verse. Professor D. Hayes Agnew was called upon to respond to the toast, "Our Fellows;" Professor T. Gaillard Thomas responded in brilliant style to the toast of "Our Associate Fellows;" Professor William Pepper, Provost of the University, Professor John Ashhurst, Jr., and Professor Theophilus Parvin respectively replied in appropriate remarks to the sentiments of "The Physician," "The Surgeon," and "The Obstetrician;" Dr. John S. Billings, U.S.A., responded to the toast to "The Medical Societies of America."

Dr. S. Weir Mitchell concluded the exercises by reading a Commemorative Ode, entitled "The Doctor's Century," which concluded as follows:

"Perchance as ghosts consultant we
May stand beside some fleshly Fellow,
And marvel what on earth he means,
When this new century's old and mellow.

"Take, then, the thought—that wisdom fades,
That knowledge dies of newer truth,
That only duty simply done
Walks always with the step of youth.

"A grander morning floods our skies
With higher aims and larger light:
Give welcome to the century new,
And to the past a glad good-night!"

A loan collection of portraits was added to those already owned by the College of former Presidents and Fellows and distinguished members of the profession, and was placed on view on Wednesday and Thursday, January 5 and 6.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

THURSDAY, DECEMBER 2, 1886.

E. E. MONTGOMERY, M.D., Vice-President, in the chair.

FIBROID TUMOR OF THE BROAD LIGAMENT.

DR. W. CONSTANTINE GOODELL exhibited for Dr. W. Goodell the right broad ligament containing an enlarged ovary, and close by its side, but distinct from it, a fibroid tumor of the shape and size of the non-gravid womb. The left ovary was also greatly enlarged. It contained a cyst which burst into the cavity of the abdomen. Since the operation she had greatly improved.

He also exhibited for Dr. W. Goodell an

INTRA-LIGAMENTOUS OVARIAN CYST,

with the following history. The girl, aged 18, had been growing large for two years, and her health also began to fail; but a tumor was not suspected until six months ago, when she was examined by Dr. George H. Woods, of Pine Grove Mills, Pennsylvania. Discovering a cyst, he sent her to Dr. W. Goodell. The operation was performed on September 25, at his private hospital, and was a difficult one, because most of the cyst lay between the folds of the right broad ligament, and the rest of it was adherent at every point to intestines and abdominal wall. It was enucleated so completely that no pedicle was left to tie. He exhibited it mainly to show the greatly hypertrophied and dilated oviduct, the walls of which were very thick and were filled with pus. The left ovary, being of the size of a goose's egg, was also removed. It contained pus, and also was enveloped in the

broad ligament, and had to be shelled out. In spite of the complications, this case recovered promptly.

Dr. W. Goodell had had during the past year another case of intra-ligamentous cyst of the most formidable character. The cyst was attached to nearly the whole of the colon, to the small intestines, to the bladder, and to the whole surface of the womb, measuring five inches in length. The lower portion lay between two layers of the broad ligament, from which it was shelled out without a pedicle. The parts were so disorganized that the second ovary could not be found, nor was it possible to determine positively which ovary was removed. But the presumption is that it was the right, because nearly the whole of the right ureter, fully ten inches of it, had to be carefully dissected off from the cyst-wall and from between the layers of the broad ligament. Many ligatures were used, and very little blood was lost; but the patient died on the table from shock while the wound was being closed. Before this death, Dr. W. Goodell had had twenty-two successive ovariotomies, all of which recovered, and he has had eight successful cases since, making in all thirty cases with but a single death.

Dr. JOHN M. TAYLOR, upon invitation from the chair, remarked that the first case reported by Dr. Goodell had been originally under his care. He had attended her in labor, and nothing abnormal occurred in the puerperal period. He had examined her six weeks later, as is his custom, and found nothing wrong. Some months afterwards she had a miscarriage; there was some placental retention, and it was followed by ovarian tenderness and signs of inflammation, which gradually increased; the ovaries became enlarged. Nine months after the miscarriage the operation was performed. An interesting question is, When did the tumor begin?

Dr. MONTGOMERY remarked that there was a resemblance between the tumor and one horn of a uterus bicornus. Was there a distinct separation between the uterus and the tumor, or could it have been such a horn?

Dr. W. C. GOODELL stated that the tumor was separated from the uterus by an inch. The tumor has greatly diminished in size since it was placed in alcohol.

Dr. HOWARD A. KELLY exhibited a

PAROVARIAN CYST

weighing thirty-seven pounds. The patient, a young woman, nulliparous, had noticed the tumor one year before. The character of the percussion-wave and the evenness of the belly-wall decided a correct diagnosis. A point of interest was the flatness of the anterior abdominal wall, with more fulness in the flanks than the speaker had ever before observed in a cystic tumor. The tumor was removed through a two-and-a-half-inch incision. The fluid was viscid and yellowish. There were no adhesions. The broad pedicle was transfixed and tied, and over this a tie made embracing the whole. The wound was closed by silkworm-gut sutures, five to the inch, and the whole operation completed in thirty-six minutes.

It is two weeks to-day since the operation. The patient is sitting up in a rocking-chair. She has no fever at all, a pulse daily growing slower, and feels well. The cyst was one large cavity, containing several cauliflower vegetations on its inner wall. The ovary lay intact on its outer wall, and the tube, about ten inches in length, was drawn out over it.

REMOVAL OF OVARIES AND TUBES FOR SUB-INVOLUTION AND CHRONIC METRITIS.

Dr. KELLY considers the indications in this case so well defined and new that he designs making it the subject of a more detailed critical communication. The patient, about 35 years of age, had raised five children, but for several years had suffered from constant soreness of the whole hypogastrium, a spot of intense burning pain to the left of the uterus, and a constant dark leucorrhœa. The menstrual congestions greatly increased her symptoms, which were again aggravated by several early abortions. She had been under excellent treatment before coming to Dr. Kelly, and had been carefully treated by him, but with only moderate, temporary improvement. Dr. Kelly then decided to stop the menstrual function, with a view to checking the periodical determination of blood to the uterus, and finally bringing about complete involution of the organ. The operation was performed on the same day as that before described. The ovaries and tubes were removed through an incision two inches long. The ovaries were full of pea-sized follicles, and were covered with a dense capsule, and were probably (not, however, in consequence of these appearances) diseased. The speaker insisted that the operation here had no reference whatever to any disease which might be found in the appendages, but the sole indication lay in the state of the uterus; the ovaries, whether diseased or not, were removed to correct that trouble. The recovery was as perfect and free from disturbance as any slight injury, and the patient was up in the next room on the fourteenth day, when the uterus was free from tenderness and already rapidly undergoing involution.

Dr. HARRIS considered the parovarian cyst interesting on account of the character of the fluid, which was opaque and quite as thick as is usually found in ovarian cysts.

Dr. CHARLES MEIGS WILSON considered oöphorectomy a resort of doubtful propriety as a remedy for metritis; for, as the menopause occurring physiologically would not stop such an inflammation, we would scarcely expect it to be of greater benefit when the

result of an operation. He doubts the moral right of exposing the patient to the risks of abdominal section for such a condition.

Dr. KELLY remarked that one reason for the operation for the relief of metritis was the exacerbation of all the symptoms at the menstrual period. Maternity could not again be accomplished, in consequence of abortion; complete rest in bed had failed to stop them. He thinks these ovaries are diseased; ovaralgia has undoubtedly some anatomical basis, but he is not able to say how it is to be discovered; more microscopical research is needed. The history of this case excluded syphilis.

Dr. JOSEPH PRICE read a

REPORT OF THIRTY-ONE CASES OF INTRA-ABDOMINAL OPERATIONS

done without any selection, in private hospital, communicated by Dr. Stansbury Sutton, of Pittsburg, Pennsylvania.

October 27, 1883. Mrs. B. Ovariotomy, large cyst; recovered.

November 18, 1883. Mrs. O. Ovariotomy, large cyst; recovered.

December 28, 1883. Mrs. C. Ovariotomy, large cysts, extensive adhesions, tapped frequently; recovered.

February 2, 1884. Miss T. Supra-vaginal amputation of uterus with both ovaries and tubes; recovered.

February 20, 1884. Miss P. Supra-vaginal amputation of uterus with both ovaries and tubes, large fibroids of uterus; recovered.

March 20, 1884. Mrs. K. Ovariotomy, left ovary large and cystic, developed under the broad ligament and roofed over by it. The ligament was opened up to get at it. On right side a fibro-cyst of the uterus with adhesions existed. Performed supra-vaginal amputation of the uterus with the remaining ovary and tube and split the broad ligament of the left side. Recovered.

April 22, 1884. Mrs. S. Ovariotomy, large cysts, extensive adhesions, especially to the liver; had been often tapped. Liver was burned with cautery-iron over strip one inch broad by four or five inches long to stop bleeding. Incision in abdominal wall seventeen inches long. Recovered.

May 12, 1884. Mrs. D. Large sarcoma of left ovary; general chronic peritonitis with ascites; tumor fed by enormous vessels. Pedicle tied and dropped as in ovariotomy. Pulmonary clot occurred on fourth day suddenly, with temperature 99°. Died.

May 29, 1884. Mrs. G. Ovariotomy, large cyst, adhesions. Recovered.

June 24, 1884. Mrs. S. Pelvic abscess. Tait's operation (the pus was stinking). Recovered.

July 12, 1884. Miss M. Removal of subperitoneal fibroid, anterior wall. Pedicle short. Recovered.

July 12, 1884. Miss L. Supra-vaginal amputation of uterus with sixteen-pound fibroid, extensive enucleation, adhesions numerous. Died.

September 16, 1884. Mrs. R. (insane). Removed both ovaries and tubes. Cured. Recovered.

September 22, 1884. Miss J. Both ovaries and tubes removed. Died of septicæmia on fifteenth day. (Consultants pronounced it typhoid fever.)

September 24, 1884. Mrs. W. Supra-vaginal amputation of uterus and both ovaries, with fifteen-pound fibroid; extensive enucleation, vast adhesions. Tetanus. Died.

December 4, 1884. Mrs. C. Supra-vaginal amputation of uterus for large fibroid; extensive intestinal and mesenteric adhesions, and in the presence of peritonitis; very bloody operation. Shock was too great. Died.

December 17, 1884. Resection of small intestines at two points for cure of artificial anus and extensive adhesions of gut. Fatal on seventh day from renal hemorrhage. Five stones, one an inch long, were found in the kidneys post mortem. The points of resection were found with difficulty. The sutures were all covered. (My first and only other resection of intestine recovered, and is living three and a half years since operation.)

March 7, 1885. Mrs. J. Ovariotomy, large cysts; extensive adhesions; had often been tapped. Recovered.

April 7, 1885. Miss S. Exploratory incision. Recovered.

June 10, 1885. Mrs. S. Double ovariotomy. Dermoid on right side. Recovered.

June 27, 1885. Miss H. Both ovaries and tubes removed. Recovered.

July 30, 1885. Miss D. Ovariotomy, large cysts, extensive adhesions; came in in a dying condition; had been tapped very often. Died.

November 18, 1885. Mrs. B. Ovariotomy, incomplete small cyst, size of cocoanut. As it was impossible to remove the cyst on account of adhesions, it was emptied, dried out, and lining well mopped with a five-per-cent. carbolic. Recovered, and cyst has not refilled.

November 19, 1885. Mrs. M. Oöphorectomy, right ovary and tube. Recovered.

November 24, 1885. Mrs. W. Double ovariotomy, large cysts, bad adhesions; patient very anæmic and feeble; had been tapped often. Recovered from operation, but died of perinephritic abscess three months afterwards.

January 9, 1886. Miss N. G. Oöphorectomy, pyosalpinx. Recovered.

March 23, 1886. Mrs. R. Oöphorectomy, right ovary and tube. Recovered.

April 3, 1886. Mrs. N. Oöphorectomy, both ovaries and tubes; kidneys contracted. Uræmic poisoning a week after operation. Coma. Death.

October 1, 1886. Miss S. Oöphorectomy, right ovary and tube; chronic ovaritis and

salpingitis. Had to dig the ovary and tube out of a mass of adhesions; bad case. Recovered.

November 20, 1886. Mrs. N. Double ovariotomy; removed large parovarian cyst and cystic ovary on left side, and cystic ovary on right side. Recovered.

This list of thirty-one abdominal sections are all I have made in my private hospital during the three years of its existence. I have never used spray over a wound, and only occasionally in my earlier cases I used two-and-a-half-per-cent. carbolic solution over the instrument. Long ago I quit this, and have used no chemical during the operation. After closing the wound, I am in the habit of dressing it with iodoform-gauze. Our wounds all heal by first intention. A great many of these patients had neither health, strength, nor money when they came to us. Rich or poor, all have had the same chance for life. All the provisions of cleanliness known to science and art are practised in my institution. With our present good condition, I believe we can save ninety-eight per cent. of ovariotomies sent within a year or eighteen months from the time the disease begins, and without having been tapped. We never lose a case if in fair condition, and if no trocar has been previously introduced into the cyst.

In this list there were thirteen ovariotomies for large cysts, and in one case a supra-vaginal hysterectomy was also done. Of these thirteen cases, two died: one of the two three months after operation, and the other was in the last stages of exhaustion when she was brought in on a stretcher.

Of the cases of supra-vaginal amputation of the uterus and both ovaries there were six; in one an ovariotomy was also done for large cysts. Of these cases, three recovered and three died.

The Tait operation for large pelvic abscess recovered.

The intestinal resection was not lost through the operation. The removal of the uterine appendages shows a mortality of two cases; one was due to operation, I think, the other was not.

I am sure that, as we gain experience in further operative work and exercise more care in rejecting cases with bad kidneys, our results here will compare favorably with others. Thus far we have refused no patient willing to enter the list for operation, and I am sure that no operator, East or West, is likely to meet with worse cases than are contained in this list.

Summary.—Ovariotomies, McDowell operations, 13; oöphorectomies, Hegar-Tait operations, 8; laparotomy for pelvic abscess, Tait operation, 1; resection of intestine, 1; removal of large solid sarcoma of ovary, 1; supra-vaginal amputation of uterus and both ovaries, 6; exploratory incision, 1; removal of subperitoneal fibroid of uterus, 1. (One case is counted twice: first as an ovariotomy for large cysts complicated with supra-vaginal amputation for fibro-cyst of uterus; secondly, as a supra-vaginal amputation of uterus complicated by ovariotomy.)

In looking over my ovariotomy cases which have recovered during the last ten years, I find that eight children have been born to them. My last laparotomy (forty-sixth) for all diseases yet attacked by operation by me was a large parovarian cyst with both ovaries cystic. The cyst and both ovaries were removed through a two-inch incision, the dressing completed, and the woman in bed in thirty minutes, without any haste. She has taken no drugs, not a drop of anything. Temperature on the fourth day was normal, and pulse 76. Wound completely healed. Experience, with honest precautions, coupled to a possibility of earlier operations and a discontinuance of tapping, will result in as good statistics in this country as abroad.

Dr. H. A. KELLY remarked that Dr. Sutton's account of his cases is very interesting, and in many particulars instructive, and better results for general work, handling all classes of cases without selection, certainly cannot be found in our country. He, Dr. Kelly, called especial attention to the note by Dr. Sutton that his ovariotomy patients have borne eight babies within the past ten years. This fact is significant as deciding a question which has been discussed in terms of vague generalization and sentimentality: "The other ovary."

About a year ago, when writing a paper upon ovarian cysts of large size, Dr. Kelly found facts in Sir Spencer Wells's table which determined this question for him upon a solid scientific basis. Of Sir Spencer Wells's 1000 cases, 768 recovered; and, deducting from these 343 over forty years of age as beyond the child-bearing period, we have left 371; again deducting 20 more, which was about the number of double ovariotomies under forty years recovered, we have left about 351 women survivors with one ovary and in a child-bearing condition. As an actual fact, 117, or about one-third, did bear children, to number 228, or a fertility of about 65 per cent. to the total number of survivors. This is then clearly the advantage of leaving one ovary in 351 women: to wit, 228 children. Now, what are the disadvantages? Obviously a return of the tumor in the other ovary and death from the second operation.

In 7 of these 351 women a second operation was necessary, and one of the seven died of a tumor doubtfully uterine.

Here, then, is the status of "the one ovary" case: *one doubtful death* of a woman seven years after her first operation against *two hundred and twenty-eight children born!*

Dr. Kelly could not accept the diagnosis of death from typhoid fever in a surgical case within three weeks of operation in the

absence of careful post-mortem examination. The typhoid condition is so common in all cases of peritonitis tending to a lethal end, and true typhoid fever so extraordinarily rare, that he rejected the diagnosis not subsequently confirmed. It savors too much of the many cases of women coming to his office week after week, stating that they "have never been well since their last confinement, when they had typhoid fever." Dr. Sutton, however, does not himself make this assertion.

Dr. COFFEE, of Pittsburg, drew attention to a case under his own observation in which typhoid fever of distinct character followed close upon a surgical operation.

Dr. M. PRICE spoke of a case in which typhoid fever followed immediately after an attack of smallpox.

Dr. JOSEPH PRICE reported a case of

HYSTERECTOMY FOR MYOMA.

The patient had applied to Dr. J. R. Haynes on account of menorrhagia with hypogastric discomfort. Uterus about the size of a three months' gravid uterus. She became very much prostrated, and suffered from sciatica in the right leg. The tumor grew rapidly, and seven months after first seeing her the tumor was found to extend from the umbilicus to the perineum, resembling in shape and position the gravid uterus at seven months. Two inches below the umbilicus and to the left a bruit was distinctly heard. Fœtal heart-sounds could apparently be distinctly heard beating 125 per minute, but they were synchronous with the patient's pulse. The lower portion of the tumor extended into the vagina almost to the perineum, and resembled very much a fœtal head surrounded by a small quantity of fluid. The os uteri could be felt only with the utmost difficulty behind the centre of the os pubis.

November 19, Dr. J. Price performed abdominal section. Before operation her pulse was 150, and temperature 100°. Six syringefuls of brandy were given hypodermically. The operation lasted about an hour. The patient slept well that night and improved in condition for a few hours, after which vomiting occurred, followed by great restlessness, pain, and increased frequency of pulse. Peritonitis developed, and the patient died at 7 A.M., about thirty-one hours after the operation. Post-mortem examination showed nearly a pint of bloody serum in the peritoneal cavity.

Dr. Price remarked that, in reviewing the operation, he felt that, with one exception, he had nothing to regret; but he did regret that he had not introduced a drainage-tube. His reason for not using it was the complete absence of bloody stain in the last abdominal washings; but it is his rule to use a drain whenever there have been adhesions to separate; he had three tubes in use in other patients at that very time; he feels assured that if he had used a drainage-tube in this case the woman would have recovered.

Dr. H. A. KELLY considered the important error in this case was the neglect to insert a drainage-tube, and gladly made this subject the text of a few remarks. Operators at large should by this time have reached a common understanding as to just how and when the drainage-tube should be used. In the *first* place, whenever there is any denuded area as large as the palm of the hand, or smaller, if there be a tendency to weep, a tube should be introduced, and sometimes, when least expected, several ounces of serum will well up through the tube daily, and the absorptive powers be saved a severe tax. *Secondly, whenever in doubt, use the tube;* no harm ever comes from it when guarded with the antiseptic precautions now in common use.

His own plan is as follows. Pass all the silk sutures as if the whole length of the incision were about to be closed; slip in the drainage-tube (he prefers a straight glass one under ordinary circumstances), and run down the shot and close the wound to the tube; but the two sutures passing through the track of the tube are left long, to be used after removal of the tube. He then once or twice a day draws out all serum accumulated in the pelvis, by means of a long-nozzled uterine syringe; when all discharge has ceased, provided it has been but sweet, clean serum, he withdraws the tube, and, running the shot down on the two unused sutures, closes the wound perfectly, leaving only a linear cicatrix, instead of a deep pit, at the lower angle, to be filled up by granulation and a large plug of scar-tissue: this is also safe after suppuration, provided all suppuration has entirely ceased.

He does not like Koeberlé's clamp, which had been used by Dr. Price in this case, and considers it far more dangerous in every way than the elastic ligature. Sänger's device, just announced, combining an extra- and intra-peritoneal treatment, promises much, and is certainly destined to repeated trial.

Dr. MONTGOMERY thought the case one of extreme interest in point of diagnosis and treatment. The pressure of the tumor on the ureters causes changes in them, and also sacculation of the kidneys. He had operated in a similar case some years ago, and a subsequent examination revealed sacculated kidneys and pus in one: even if no knife had been used, the patient would have died from the ether. He thinks, with Dr. Price, that the drainage-tube should have been used in his case.

Dr. JOSEPH PRICE remarked that he had no fear whatever of the drainage-tube, and thought it might be used in every case. Tait's rule, "When in doubt, use the tube," was a good one. Dr. Price made some remarks upon his method of using drainage-tubes of glass, employing cotton wick in some cases to

remove accumulations of serum and to clear the openings of the tubes, using a sucking bulb with gum tubing to draw out fluid accumulations, and introducing a smaller gum tube through the glass one before withdrawing the latter.

Dr. M. PRICE exhibited specimens from a case of

PYOSALPINX

of gonorrhœal origin. Is pyosalpinx not almost always the result of gonorrhœa? His cases have without exception followed attacks of gonorrhœa. Can such a sequel be anticipated and prevented?

Dr. MONTGOMERY remarked that Dr. Noeggerath initiated the idea of latent gonorrhœa as the cause of salpingitis and pelvic peritonitis.

Dr. M. PRICE remarked that his patients had been in robust health; they were generally women who had borne but one child, and the labor had been followed by repeated attacks of peritonitis.

Dr. LONGAKER read a report of a case of

LAPAROTOMY FOR PYOSALPINGITIS.

Maggie T., aged 33, was admitted to Lying-in Charity Hospital November 13, 1886. She had one child eighteen years before, after a difficult and prolonged labor. Unmarried, and has a history of specific disease. During the last four years her periods had been accompanied by intense suffering, and in the intervals she was never free from distressing aches in the pelvis. Lately she had used opium to some extent. In addition to the evident enlargement of the appendages on both sides, the patient has a perineo-recto-vaginal fistula and a stricture of the lower end of the rectum. A diagnosis of pelvic cellulitis was made by him in this case two years ago.

Operation.—November 18. The left tube, a sausage-shaped tumor, and the ovary, a fluctuating mass the size of a walnut, were easily removed: a small amount of pus escaped from the end after ligation, but this was arrested by pressure-forceps. The ligature was necessarily passed near the uterus, but, owing to friability of tissues, troublesome oozing continued and delayed the closure of the abdomen. On the right side the ovary and tube formed a huge abscess the size of a goose-egg. It was impossible to separate and remove this without rupture. It was filled with pus and altered blood. Adhesions were dense and firm. There was also some oozing on this side, but it gave rise to comparatively little trouble. The peritoneal cavity was irrigated with hot water; one to five thousand bichloride solution in sponges; abdominal walls sutured with silk, over which was placed an impervious coat of iodoform collodion. Convalescence uneventful. She is now free from pain.

Dr. M. PRICE inquired about the source of hemorrhage. He had seen serious hemorrhages due to the fact that the tube was cut by the ligature. He thought it important to tie straight across the tube, and not obliquely. He ligates by double ligature and ties back. He considers it right to open up at once if hemorrhage is at all free; he does not think it right to trust to sponges and hot water.

Dr. JOSEPH PRICE had seen very free hemorrhage from adhesions to the bowels, large sinuses being laid open and pouring out blood. In several cases he had used iron as a styptic.

Dr. LONGAKER explained that the hemorrhage came from the opening up of the broad ligaments.

Dr. H. A. KELLY read a paper embracing

NOTES ON PALPATION OF THE FEMALE URETERS,

which will be published in full with diagrams.

Dr. JOSEPH PRICE read an interesting letter from Dr. Joseph Eastman, summarizing the features of McDowell's early operations, showing how perfectly antiseptic his work was.

Dr. COFFEE spoke of Dr. Sutton's work as being pioneer work. He gave up good practice and went to Europe to work up this field.

W. H. H. GITHENS,
Secretary.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 2, 1886, the President, A. JACOBI, M.D., in the chair.

PARENCHYMATOUS INJECTIONS OF CARBOLIZED IODINE INTO A PHTHISICAL LUNG.

Dr. J. BLAKE WHITE presented a phthisical lung, the patient having died six weeks after the last of three injections of a solution of carbolized iodine into a large cavity. The patient was an inmate of Charity Hospital, and had advanced phthisis, with emaciation, loss of strength, irritating cough, expectoration, night-sweats, etc. In July last Dr. White had made the first injection of ten minims of a solution of carbolized iodine, with a little morphine and atropia, through the first intercostal space on the left side, where there were the physical signs of a pulmonary cavity. The second injection was made about a week later, and the third and last one, consisting of twenty-five minims of the solution, a few days later. At this time Dr. White's term of service expired and the treatment was discontinued. The result of the treatment was a temporary improvement in all the symptoms, and no reaction followed: the cough was controlled, the expectoration lessened, the night-sweats checked, the appetite improved, suppuration in the cavity antagonized, and cicatrization promoted. The lung was shown in verification of the latter of these state-

ments. Intra-pulmonary medication in consumption seemed to the reporter a very rational treatment, and experience thus far had demonstrated that it was.

LARYNGEAL DIPHTHERIA—INTUBATION AND PATHOLOGICAL ANATOMY.

Dr. W. P. NORTHRUP read a paper on this subject. He first spoke of the efforts of Bouchut, of Paris, to introduce a method of intubation of the larynx in 1858, and the disfavor with which it was received by Trousseau and the profession in that country in general. Bouchut's work was unknown to Dr. O'Dwyer, of New York, when that gentleman some years ago was led, by an unusually high mortality after tracheotomy in the New York Foundling Asylum, to try intubation of the larynx, beginning his experiments on the cadaver. The result of his efforts had been highly successful, and to a consideration of his method and the pathological findings in eighty-seven cases of death from laryngeal diphtheria in the above-named institution Dr. Northrup's paper was devoted.

The records given consisted of all the cases of death during the past five years in the New York Foundling Asylum from laryngeal diphtheria. The whole number of children under the care of the institution during that time was eighteen hundred, eleven hundred being taken charge of by the nurses within and immediately about the institution. The entire number of deaths from laryngeal diphtheria had been eighty-seven: the number of males being thirty-seven, of females fifty. The average age of the patients was two years and seven months. The greatest number of deaths took place between the third and fourth years.

Fifty-six of the eighty-seven cases began with symptoms indicating that the membrane made its appearance in the larynx either before or simultaneously with its appearance in the pharynx; in thirty-one cases the average number of days before the commencement of symptoms of croup was two and a quarter; in fifty-four cases the average time from the beginning of croupy symptoms until death was three and four-fifths days. Of the eighty-seven cases the number accompanying or following measles was twenty-two; scarlet fever, eight; varicella and scarlet fever, one; in fifty-four cases there was pneumonia. In most of the cases where the lesions were not plainly declared a diagnosis had been made based on microscopic and post-mortem examination. The question of pulmonary collapse and pneumonia had been constantly in mind, and signs of parenchymatous inflammation or pneumonitis had been present, as a rule. It would fail of the truth to call the condition of the lung a bronchitis; it would fail still further of the truth to call it collapse; the lesion was broncho-pneumonia. In considering the cause of death when there was such a complication of lesions,—sepsis, bronchitis, pneumonia, and nephritis,—there was little satisfaction in attributing it to any one of them separately. Twenty-seven of the eighty-seven patients were believed to have died from extension of the diphtheria into the bronchi; twenty-nine had sufficient pneumonia to account easily for the death.

The highest temperature in nineteen cases was 104°; in fifteen it was 105°; in three, 106°; in two, 103°; and in one, 107°.

The distribution of the membrane was as follows: in nine cases it extended from the tip of the nose to the finest bronchi; in six cases, from the nose to the bifurcation of the trachea; in seventeen, from the pharynx to the finest bronchi; in seventeen, from the larynx to the finest bronchi; in seventeen, from the pharynx to the main bronchi; in seventeen, in the larynx and trachea; in three, in the pharynx and larynx; in one, in the larynx only.

Interstitial emphysema was found in eight cases, pronounced vesicular distention in nine. The interstitial emphysema was located principally in the anterior portion of the upper lobes and roots; the vesicular, mainly in the anterior portion of the upper lobe. It might be remarked that interstitial emphysema had been met with quite as often in marasmus as in any other condition, except whooping-cough.

The instruments used by Dr. O'Dwyer for intubation of the larynx consist of the larynx-tubes, the introducer, the mouth-gag, the extractor, and the scale to indicate the size to be used according to the age of the patient. Instructions for their use accompany the set of instruments, which were manufactured by Tiemann & Co.

The following were some of the advantages of intubation of the larynx. It relieved dyspnœa due to laryngeal stenosis; the parents and friends offered no objection to the procedure, as they did against tracheotomy; it was a comparatively simple operation, free from danger, and did not require an anæsthetic; no fresh wound was added, and no trained assistant was required at or after the operation; the air entered the lungs moist and warm. The procedure did not preclude tracheotomy, and if this should prove necessary the laryngeal tube would offer a guide to cut down upon. The objections were that the tube rendered the swallowing of fluids embarrassing, although as a rule the child soon learned to swallow very well. One case had proved that there might be danger of obstructing the trachea by pushing the membrane before the tube. Intubation of the larynx might also be employed in other cases of laryngeal dyspnœa, as in syphilis, etc. The relief to the obstructed breathing was always very striking, and greatly encouraged the parents, but the physician should not give a favorable prognosis for forty-eight

hours, as serious complications might develop although the case had progressed well until the fortieth hour after relief of the dyspnœa.

The value of the procedure was manifest in the fact that twenty-eight and a half per cent. of the one hundred and sixty-five reported cases of intubation of the larynx for laryngeal diphtheria had recovered. He would not give statistics of recoveries after tracheotomy for the same condition, as those of different authors were so conflicting, but he thought they were not as favorable as those of intubation.

Dr. Francis Huber related eleven cases of laryngeal diphtheria in which he had done intubation of the larynx late in the disease, after there had been well-marked stenosis, and four of the eleven had recovered; one was still wearing the tube; the other five had died. Dr. Denhard, he said, had also performed the operation in eleven cases, five having recovered.

Remarks were also made by Drs. A. S. Hunter, Partridge, and Caillé.

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held November 24, 1886, the President, John A. Wyeth, M.D., in the chair.

MILIARY ANEURISMS IN THE BRAIN.

Dr. R. Van Santvoord presented microscopic slides showing miliary aneurisms in the brain of a man who died with cerebral hemorrhage, and at the autopsy there were found six or seven cortical hemorrhages. After macerating the brain for a time, he took hold of both carotids and pulled out quickly a leash of vessels which, on being washed, showed six diseased branches.

CALCIFICATION OF THE AORTIC VALVES.

Dr. Van Santvoord presented the heart of a woman who claimed to have been only 55 years of age, but appeared much older. Her chief symptom was marked feebleness of the heart. The autopsy showed pulmonary phthisis, œdema of the brain, fatty liver, chronic diffuse nephritis, and tubercle in the spleen. The left ventricle was slightly hypertrophied and dilated, and contained a number of thrombi, firm and nearly white. The aortic valves showed advanced calcification. The cardiac muscle was fatty. There was œdema of the lungs, and Dr. Van Santvoord thought the case supported the conclusion arrived at by Dr. W. H. Welch from experiments, that œdema of the lungs often accompanied marked weakness of the left ventricle.

AORTIC REGURGITATION (FROM RUPTURE OF A VALVE?).

Dr. Van Santvoord presented the heart of a man, 44 years old, who during nine years had been an inmate of the Randall's Island Insane Asylum. He had formerly been a driver of a brewery-wagon. He was found to be suffering from an acute nephritis, which became complicated by pericarditis and ended fatally. A typical double aortic murmur was heard; there was also a systolic murmur at the apex, not transmitted to the left. A cardiac functional murmur was heard four days prior to death. The autopsy showed slight thickening of the arachnoid and anæmia of the brain. The lungs were very œdematous. There were lesions in other organs, but those of chief interest related to the heart. The pericardium contained about two ounces of clear fluid. Both layers of the pericardium were coated with yellow lymph. The right cavities were apparently normal. The left ventricle was considerably dilated and hypertrophied. Two leaflets of the aortic valve were only slightly thickened. The third, corresponding to the right coronary artery, showed a notch at one side of the corpus arantii. From one side of this notch projected three fibrous vegetations; from the other one, about one inch long. The mitral orifice admitted the ends of three fingers. The valves looked normal. The aorta showed extensive atheroma; it was not dilated. From the fact that two of the leaflets were only slightly thickened, from the notch-shaped lesion and limitation of the fibrinous outgrowth to the edges of this notch, it seemed probable that the lesion was caused by a rupture of the valve. Compensation of the cardiac lesion was apparently good prior to the patient's last illness. It seemed plausible to suppose that the extra strain thrown on the aorta by the cardiac systole, which was necessary to maintain this compensation, was a factor of importance in increasing the atheroma of the aorta. The valves, being subject to a subnormal strain on account of regurgitation, did not share in this factor, and so the unusual disproportion between the general disease of the valves and of the aorta might be supposed to have arisen.

Dr. H. J. Boldt presented a slough from the uterus produced by the use of chloride-of-zinc cotton after curetting the cavity in a case of carcinoma.

BILIARY COLIC—ULCERATION OF THE GALL-BLADDER.

Dr. L. E. Holt presented several medium-sized gall-stones which were found at autopsy in a case chiefly interesting in connection with the clinical history. The patient gave a history of biliary colic with jaundice. On the 8th of July last he was taken with extreme pain in the region of the stomach and right hypochondrium. The following day he had symptoms of acute gastro-enteritis and was jaundiced. At the end of ten days he had another attack, and from that time began to lose flesh and strength, and had more or less

fever. One day he had a violent chill, and the temperature rose to 104°. There being a history of malarial poisoning, quinine was given; but three days later the temperature rose again, and remained more or less elevated until death. The lesions of chief interest were the following: the stomach, duodenum, and two or three feet of the jejunum showed marked acute inflammation. The hepatic and common bile-ducts were pervious. The jaundice was apparently due to obstruction at the opening of the common duct into the duodenum, caused by the swollen condition of the mucous membrane. The gall-stones had ulcerated through the gall-bladder, exciting a localized peritonitis and becoming encysted in an abscess on the under surface of the liver, close to the gall-bladder. Death seemed to have been due to septic absorption from this abscess.

EXSECTION OF THE TIBIA FOR OSTEOMYELITIS.

The PRESIDENT presented the portion of the tibia lying between the epiphyses, removed by operation from a boy 12 years of age, who had been the subject of osteomyelitis. The periosteum was saved, and it was hoped there would be reproduction of the bone. This was the last of nine cases of destructive osteitis of the tibia in which he had operated within fourteen months. From two to four inches of the tibia were removed in the several cases, and all the patients had recovered with reproduction of bone except one, who returned with the tibia absent to the extent of about four inches. This patient was again admitted to the hospital, and Dr. Wyeth attempted to convert the tibia and fibula into a single bone by removing a thin piece at their articulating surface and wiring them together. It might be necessary to perform a similar operation at the other articulation. Dr. Wyeth thought there was scarcely a condition of osteitis of the tibia in which amputation was justifiable.

COCAINE IN MINOR SURGERY.

Dr. WYETH also presented a lipoma and a small cystic tumor removed from the forehead, and made them the basis of some remarks upon the value of the local use of cocaine as an anæsthetic in minor surgery. He had operated by this method of producing anæsthesia in a number of similar cases, and in cases of ingrowing toe-nails, circumcision, hemorrhoids, fistula in ano, etc., without producing pain. He had injected as much as three or four grains at a single operation without injurious effects. He employed a four-per-cent. solution.

Dr. BOLDT had seen less than one grain of cocaine injected into the region of the trifacial nerve produce serious shock.

Dr. LOCKWOOD recalled a case in which cocaine-poisoning was produced by the injection into the neck of twenty minims of a four-per-cent. solution preparatory to tracheotomy.

Dr. WYETH thought it unsafe to give ether or chloroform immediately after failure with cocaine.

Dr. HOLT had seen very unpleasant symptoms follow the injection of twenty minims of a four-per-cent. solution in a child.

Dr. SCHIFF had seen its use followed by sloughing in two cases of circumcision, and by parenchymatous hemorrhage in the case of another operation of an hour's duration.

A stated meeting was held December 8, 1886, the President, JOHN A. WYETH, M.D., in the chair.

CHRONIC ENDARTERITIS.

Dr. T. MITCHELL PRUDDEN presented the aorta and arteries of the brain removed from the body of a man of middle age, who died a few hours after being brought to the hospital in an ambulance, with apparent right hemiplegia. The interest in the case related to the very marked changes in the aorta and arteries of the brain, without lesions of other organs. There were numerous large patches of atheroma and fatty degeneration of the aorta, and nearly all of the cerebral arteries, including the finer ramifications, showed similar lesions. The arteries of the brain were obtained nearly complete by macerating the brain for a few days in water and then washing in a current.

Dr. PRUDDEN also presented a set of specimens illustrating the

BACTERIA OF TYPHOID FEVER.

Dr. CUSHIER presented a

FIBRO-SARCOMA OF THE PAROVARIUM

removed from a woman 37 years of age, married nine years, but never pregnant. Her general health had been excellent until a year ago last September, when the abdomen grew rapidly in size following a strain. The following March it diminished in size, and she was again able to go about. The latter part of last summer it increased rapidly in size again, and in November Dr. Cushier was consulted, who found a distention of the abdomen due apparently to an encysted dropsy, and a diagnosis of possible ovarian or parovarian cyst was made. On the 12th of November the abdomen was opened, and two very thin walled cysts burst as soon as touched. The principal tumor had a long pedicle, and in removing it a part of the ovary was cut through. The pedicle was found to consist of a number of tubes, as many as five, which admitted a probe, and ended in a blind extremity at the tumor. The fluid into which the tumor was placed de-

stroyed the lining membrane of these, which rendered them unfit for microscopical examination, but they were believed to have developed from the ducts of the Fallopian tube. The tumor itself was a spindle-celled fibro-sarcoma.

Dr. VAN GIESSEN presented

SECTIONS OF THE SPINAL CORD,

made at various points, and illustrating poliomyelitis anterior and tubercle.

TUMOR OF THE PALATE.

Dr. ROBERT NEWMAN presented a tumor, the size of an almond, removed from the junction of the hard and soft palates in a woman, 55 years of age, who had noticed the tumor during the past twenty years. Recently it had increased in size and given trouble. It was removed, without pain, after a dose of whiskey and the local application of cocaine. Dr. Newman remarked concerning the use of cocaine, that he had in one case injected twenty-five minims of a four-per-cent. solution into the bladder, which was immediately followed by a bursting sensation in the head which had now lasted ten days. The tumor was referred to the Committee on Microscopy.

A stated meeting was held December 22, 1886, the President, JOHN A. WYETH, M.D., in the chair.

RED ATROPHY OF THE LIVER—CIRRHOSIS OF THE KIDNEYS—THICKENING OF THE VESSELS AT THE BASE OF THE BRAIN.

Dr. W. H. PORTER presented the specimens for a candidate.

Dr. W. M. CARPENTER presented for a candidate specimens illustrating pyosalpingitis.

SYPHILITIC CHANGES IN THE LUNGS.

Dr. W. H. PORTER presented a lung which contained several tumors believed to be syphilitic gummata. He also exhibited a pair of lungs which were the seat of very extensive infiltration by the same material. Examination for the tubercle-bacillus had been carefully made, but without finding it. The clinical history in these cases showed scarcely any, if any, elevation of temperature, and this fact he attributed to the marked thickening of the alveolar walls throughout the lung, preventing entrance of the broken-down material into the lymph-sacs (with attending septic fever) and directing it into the bronchi; hence also the profuse expectoration. In tuberculosis the fever was due, he thought, to the easy access of the pus into the lymph-vessels causing septicæmia.

CASTRATION FOR SUPPURATING ORCHITIS, PROBABLY OF SYPHILITIC ORIGIN.

Dr. SCHIFF presented the testicle removed from a man who had, about six months before, been exposed at sexual intercourse. He first had gonorrhœa and two successive attacks of epididymitis. About a month after the exposure he had the initial lesion of syphilis, and within two months more had alopecia, gummatæ, and syphilitic condylomata about the anus. The testicle was extirpated three days ago, or about six months after the exposure to syphilis and gonorrhœa. Eight ounces of pus were evacuated. Dr. Schiff thought the orchitis was syphilitic.

PYOSALPINGITIS.

Dr. J. H. BOLDT presented the uterine appendages of one side removed for pyosalpinx in a woman who had complained of severe pain on the opposite side, where no disease was recognized. He also presented the organs removed in another case of unilateral pyosalpingitis. It was more common to find disease on both sides.

URETHRAL CALCULUS.

Dr. BOLDT presented a urethral calculus as large as a large pea, removed from near the meatus in a boy, aged 14 years, whose symptoms, consisting of severe pain and scanty micturition, began in 1875. He was for three months in Roosevelt Hospital, and was discharged incurable. Since 1877 he had had convulsions which the father described as epileptic. The operation for removal of the stone was performed only about four days ago, but the patient since that time had had no more trouble. Dr. Boldt thought the stone was too small to interfere with the flow of the stream if its location had been in the bladder; he therefore thought it had been during those years in the urethra, gradually growing larger. Nothing abnormal had been noticed in the urine; no stones could be felt in the bladder.

CARCINOMA OF THE VERTEBRÆ.

Dr. AMIDON presented a part of the vertebræ removed from the body of a man, aged 40, who was a clerk, accustomed to lifting heavy boxes, to which fact pains considered to be due to lumbago had been attributed. In March last he suffered from pain in the right side and leg, and later in the left side, chest, and abdomen; there was pain on pressure over the spinal column, most marked at the last dorsal vertebra; there seemed to be small nodules and hardening of the liver; the lymphatic glands were enlarged. A diagnosis of cancer of the spine was made. The autopsy showed almost complete destruction of the sacrum, and disintegration and infiltration of the lumbar and last dorsal vertebræ, most marked in the last dorsal. There were small nodules in the liver, and also infiltration at one point in the lung which had given physical signs during life. The microscopical examination was made by himself and by Dr. Ferguson, who considered the tissue to be cancerous. Dr. Amidon referred to two other

cases of cancer of the spinal column, in each of which there was pain on pressure, and also to the case of a little girl suffering from a tuberculous tumor of the spine in whom there was pain on pressure, and he concluded that the rule was not based on fact which attributed tenderness on pressure over the spine to a functional rather than to an organic lesion. He would say that the pain in the case reported was due to pressure of the cancerous material upon the spinal nerves as they passed through the intervertebral foramina; he believed the cancer of the vertebræ to be primary.

Dr. PRUDDEN remarked that it was not uncommon for the secondary deposit of cancer to be larger and more destructive than the primary, and he saw no reason for not regarding the tumors in the liver as of primary origin, and the deposit in the vertebræ as secondary, in Dr. Amidon's case. Primary cancer of bones was very rare, if indeed it ever occurred.

Cases of cancer of the vertebræ were related by Drs. MENDELSON, BOLDT, PORTER, and the PRESIDENT.

Dr. PORTER said that the more extensive the deposit the more likely was it to be sarcoma, not carcinoma.

MISCELLANY.

PHILADELPHIA COUNTY MEDICAL SOCIETY.—At the annual meeting for the election of officers, held January 5, the following were duly elected for the ensuing year:

President.—J. Solis-Cohen.
Vice-Presidents.—W. W. Keen, E. T. Bruen.
Treasurer.—L. K. Baldwin.
Corresponding Secretary.—M. S. French.
Recording Secretary.—S. Solis-Cohen.
Reporting Secretary.—W. H. Morrison.
Assistant Secretary.—A. C. W. Beecher.
Librarian.—C. W. Dulles.
Censors.—W. Joseph Hearn and DeForest Willard.

HYDROGEN DIOXIDE IN CATARRHAL AFFECTIONS.—Dr. John N. Mackenzie directs attention to the use of hydrogen dioxide in four-per-cent. solution for catarrhal affections attended by profuse muco-purulent discharge, used in doses of a fourth to half an ounce three, four, or even six times a day; for topical use he prefers a six-per-cent. solution. By some persons even weaker solutions cannot be used, on account of their irritating effect upon the air-passages. A marked improvement in the gastric functions was incidentally observed during its administration. Indeed, so striking has been its effect in this regard that it is worthy of more extended trial in obstinate stomachic derangement.—*Practice.*

NINTH INTERNATIONAL MEDICAL CONGRESS.—We are gratified to learn that Dr. Mariano Semmola, Professor of Experimental Therapeutics in the University of Naples, Italy, has accepted the invitation to deliver one of the "General Addresses" before the Congress, and that his subject will be "Bacteriology and its Clinical Therapeutics."

DR. JOHN B. DEAVER has been elected one of the Attending Surgeons to the Philadelphia Hospital, and Drs. Roberts Bartholow and Charles K. Mills, Neurologists to the same institution.

DR. F. A. PACKARD has been elected one of the Resident Physicians at the Pennsylvania Hospital.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM DECEMBER 19, 1886, TO DECEMBER 31, 1886.

MAJOR W. H. FORWOOD, SURGEON.—Granted leave of absence for one month. S. O. 129, Department of Dakota, December 16, 1886.

MAJOR EGON A. KOERPER, SURGEON, U.S. ARMY.—Granted leave of absence for two months, to take effect about January 1, 1887. S. O. 297, A. G. O., December 27, 1886.

CAPTAIN J. V. LAUDERDALE, ASSISTANT-SURGEON.—Ordered from Fort Concho to Fort Clark, Texas. S. O. 174, Department of Texas, December 16, 1886.

FIRST-LIEUTENANT EDWARD EVERTS, ASSISTANT-SURGEON.—Ordered from Fort Grant to Fort Apache.

FIRST-LIEUTENANT CHARLES F. MASON, ASSISTANT-SURGEON.—Ordered from Fort Huachuca to Fort McDowell.

FIRST-LIEUTENANT W. B. BANISTER, ASSISTANT-SURGEON.—Ordered from Fort Wingate to Fort Lowell.

FIRST-LIEUTENANT W. D. DIETZ, ASSISTANT-SURGEON.—Ordered from Fort Stanton to Fort Bayard. S. O. 136, Department of Arizona, December 16, 1886.

FIRST-LIEUTENANT A. S. POLHEMUS, ASSISTANT-SURGEON.—Ordered for duty as post-surgeon at Fort Gaston, California, relieving

FIRST-LIEUTENANT H. I. RAYMOND, ASSISTANT-SURGEON.—Ordered for duty at Angel Island, California. S. O. 123, Department of California, December 13, 1886.

FIRST-LIEUTENANT JOHN L. PHILLIPS, ASSISTANT-SURGEON.—Granted one month's extension of his leave of absence. S. O. 297, A. G. O., December 27, 1886.

FIRST-LIEUTENANT C. L. G. ANDERSON, ASSISTANT-SURGEON.—Assigned temporarily to duty at Whipple Barracks, Arizona. S. O. 132, Department of Arizona, December 7, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U.S. NAVY FOR THE WEEK ENDING JANUARY 1, 1887.

PASSED ASSISTANT-SURGEON F. ANDERSON.—To U.S.S. "Thetis."

ASSISTANT-SURGEON E. W. AUZAL.—Detached from Receiving-Ship "Independence," and ordered to Coast-Survey Steamer "McArthur."

PASSED ASSISTANT-SURGEON E. H. GREEN.—Detached from Naval Laboratory for temporary duty on Receiving-Ship "Independence."

PASSED ASSISTANT-SURGEON J. D. GATEWOOD.—To Naval Academy, January 5, 1887.

PHILADELPHIA, JANUARY 22, 1887.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF CEREBRAL SYPHILIS WITH GLYCOSURIA—DEATH FROM ACUTE PHTHISIS AND DIABETIC COMA.

Delivered at the Pennsylvania Hospital, November 27 and December 4, 1886,

BY PROF. J. M. DA COSTA.

GENTLEMEN,—This patient has been in the hospital for only a short time, and occupies Bed No. 9 in the Men's Medical Ward. He is a colored man, 40 years of age, and was admitted four days ago (November 23). He states that his father died with phthisis. The patient looks older than the age given, but he is of spare frame and has never been robust. When a child, he fell and struck his head, and the next day at the breakfast-table he fainted. Ever since that time he has been subject to attacks of sick headache. Four years ago he acquired syphilis. The present illness, according to his statement, began nine weeks ago, when he became subject to vertigo and rapidly lost flesh and strength. He also noticed that he was passing a great deal of urine, rising several times in the night to empty his bladder. These symptoms steadily became worse, and within a few days of admission he developed a troublesome cough.

Upon admission he was weak and emaciated, his temperature was 99°, his pulse 92, the respirations 28 per minute. In the centre of the right lung we discovered a small area of consolidation. The urine was slightly acid in reaction, clear, amber, specific gravity 1042, and contained sugar in large quantity.

He was placed temporarily—and with a view to the lung-complication rather than for any other reason—upon small doses of iodide of potassium. Since he has been in the hospital a fever has developed. On the night after he was admitted his temperature was 102.4°. On the 25th it rose to 105°, and has continued a high fever-temperature.

He is very weak and miserable, and I will ask you to note that his heart-sounds are feeble; no murmur is distinguished.

I find in the notes that on the 25th he complained of pain in the abdominal region. His temperature this morning is down to 100°: the fever-process therefore has been modified.

With regard to treatment, I will also say that the treatment was at once changed as soon as we recognized the nature of the case,—partly on account of the fever-temperature and partly on account of the disease which underlies the whole affection. He was placed on salicylate of sodium, one drachm in twenty-four hours; and whether due to the remedy or to something else, in twenty-four hours the fever-process had decidedly ameliorated. He also passed a smaller quantity of urine: it has been reduced from six pints to four pints per diem.

Upon examination of the lung this morning, I find that there is general dulness on the right side of the chest anteriorly, and it becomes more marked as we go towards the lower part of the right lung. There is harsh respiration heard over the lower part of the same lung. As we go to the side we find the same dulness that was noted on admission. There is no pleuritic effusion. There is also diminished resonance at the upper part of the left lung. His tongue is dry, cracked, and coated. His face is thin; his mind is rather dull; pulse 120 and extremely weak; he complains of everything swimming before him. It is evident that he is in a very low condition.

Now, gentlemen, we have here a case of acute diabetes before us, with a pulmonary complication and a febrile condition, and these, roughly speaking, are what we have to explain. Add to this a certain amount of drowsiness and mental dulness, coming on late in the attack, and all this in a man who was in good health nine weeks ago, and appearing without obvious explanation except a history of remote head-injury if you choose to accept the statement. I do not myself lay much stress upon it. But how shall we explain the lung-complication? Cases of acute diabetes are very apt to have attacks of consolidation of the lung, either acute broncho-pneumonia or acute phthisis. It is not generally a difficult diagnosis between the two. Careful physical examination is out of the

question now, on account of the man's weak condition; but, even without it, if, as here, there is much emaciation, cough, and apex-consolidation of the lung, we may assume that the affection is due to tubercular disease.

Returning to the question of treatment, I placed this man upon salicylate of sodium. If there is a remedy which will do good in diabetes, it is this: a long experience with salicylate of sodium in the treatment of diabetes leads me to regard this as the best in its management. I have had now a large number of cases, both here and in other public institutions and in private practice, and I have had better results with salicylate of sodium than with any other remedy. It is better than opium, and without the bad results of opium. I give from a drachm to a drachm and a half in twenty-four hours for a certain period; then stop it for a time, and go back to it again. I have noticed also, when there is diabetes and gout at the same time,—and a diabetic diet favors the development of gout,—that the salicylate of sodium enables the patient to go on with the treatment of the diabetes without exciting the attacks of gout. Again, in a case of high temperature it is particularly advantageous. You may ask, Is it the acid or the combination with the base that is so efficient? I have tested this. I have placed patients upon salicylic acid alone, and have placed them upon other sodium salts, and also upon salicylate of sodium, and have found that, although salicylic acid does good by itself, and the sodium salts undoubtedly do good, yet diabetic patients do better upon the combination than upon either singly. But these are the results of tests extending over weeks of observation, and I have not time to refer to the cases to prove this.

For the few days that we have had the case under observation we have only had time to resort to treatment for his general condition rather than any direct specific treatment. To relieve his present low condition he should have six ounces of whiskey and twelve grains of quinine daily, while we keep up the salicylate of sodium. You know that the diet of these patients is usually restricted to green vegetables and meats; but this must not be rigidly adhered to with him. He shall have oysters, eggs, and milk, but no starchy food.

One other point in conclusion: Is his weakness and mental dulness due to the phthisis? or is it a part of the effects of diabetes,—what has been called diabetic coma, or acetonæmia, and due to retention of matters in the blood which give rise to cerebral symptoms?

As the hour has expired, I will not be able to discuss the question at present, but will leave it for our next meeting.

(*Clinical lecture continued, December* 4, 1886.)

GENTLEMEN,—This morning I wish to direct your attention first to the specimens obtained from the autopsy of the case of diabetes which was before you at our last clinic in almost a comatose condition. He died on the same day. I confess that I thought that that would be the result, because, as I told you then, he had had a continued high temperature, and there were such evident signs of extreme exhaustion that we had to abandon all treatment except stimulants and measures directed towards supporting his strength. You remember that there was decided dulness on percussion at the base and at the apex of the right lung, and that there was also moderate dulness over the upper lobe of the left lung. I remarked that it was most likely of a tubercular character; and this has proved to be the case. We have here the specimens, and you can see how far the signs observed during life correspond with what we find after death. First, look at the kidneys: they are firm, swollen, not much enlarged; the cortical substance is pale, striated, and opaque. The capsule is easily removed, leaving a smooth surface. Both kidneys are alike, except that in the interior of the right a small, hard nodule is noticed, which looks like a tubercle: it will be removed for microscopic examination. With this exception, there is nothing in the kidneys which can be said to be at all out of the way. The spleen is very small and firm, weighing only two ounces; the pancreas is also small, its substance is quite pale, and it appears shrunken and atrophied; the liver weighs only two pounds ten ounces. The surface of its section smells strongly of acetone. The gall-bladder is shrunken, and contains a small quantity of pale bile. Coming to the lungs, we observe that the upper part of the left lung is consolidated, and it contains upon its cut surfaces numerous

shot-like bodies harder than the surrounding tissue; the right lung presents a similar appearance at the point over which we detected dulness. No doubt can exist as to the presence of these tubercular formations in the lung. At the apex of the left lung there is a cavity with thick walls, and at numerous other points in both lungs are areas of softening filled with fluid; no tubercle-bacilli were detected in these fluids. The aorta presents marked atheroma, with slight dilatation; the heart shows a moderate degree of hypertrophy of the left ventricle, and contains a very firm fibrinous clot; the valves are normal, except slight atheroma of those on the left side. It weighs eight ounces.

But what is more interesting is the condition of the brain. You will remember that when he was before you he was very dull and stupid; there was no improvement after you left, and he died comatose a few hours later. Let us see if there is any explanation for those symptoms. I will read the preliminary report of the pathologist, Dr. Longstreth, who intends making a careful microscopic study after the brain has been properly hardened. "On removing the skull-cap a considerable amount of serous fluid escaped from beneath the dura mater. Upon the convexity of the cerebrum there is decided opacity of the pia mater; some of the cerebral convolutions are shrunken, and in the interior part of the longitudinal fissure quite firm, old adhesions exist between the two hemispheres. The lateral ventricles contain a small amount of serous effusion; there are small transparent cysts in both choroid plexuses; the third ventricle also contains some clear fluid. The substance of the cerebrum is very firm in most parts: on section of the basal ganglia they are found to be softened in some of their layers. The cerebellum is soft throughout, except the corpus dentatum and the central white substance; the crus cerebri of the right side contains a dark-colored elliptical area which looks like an old spot of hemorrhage or the remains of a gummatous growth; below this point the crus is softened. The pons Varolii is also softened throughout, but especially on the right side, which is shrunken. The substance of the medulla oblongata is also softened—including the tissue forming the floor of the fourth ventricle—as far down as the beginning of the spinal cord. The softening here is also more marked on the right side, but the difference between the two sides is less decided than in the pons."

Now, what did this man die of? Exhaustion, clearly, with coma. There is no doubt in my mind that this patient had acetone in the urine and in his blood, as we find it here in the liver. In other words, there was acetonous formation going on in various parts of the system. The urine had a strong smell of acetone, and when examined during life gave the color-reaction with ferric chloride. The odor is one you cannot forget when once you have learned to recognize it, though it is difficult to describe. Some have thought it like the odor of chloroform, others like that of bitter almonds, with a somewhat ethereal odor at the same time.

Now, gentlemen, with the results before us, we may inquire how they correspond with the symptoms observed during life. In the first place, how do we explain the condition of acetonæmia? It simply means that there is acetone in the blood; and it has been assumed that diabetic sugar undergoes transformation into acetone and poisons the nervous system. That this substance existed both in the urine and in the blood is evident. Yet are we warranted in attaching to acetone the same importance as we do to urea in Bright's disease? Is the coma due to the presence of acetone in the blood, just as we have excess of urea in the blood in uræmia? I think not. We cannot always connect the cerebral symptoms of diabetes with the presence in the blood of acetone or any kindred substance; and the reason I say this is that I have followed up the cases, of which I have records of a number, and have found that we may have this peculiar cerebral disturbance without acetone in the urine, and we may have a decided amount of acetonuria without the occurrence of coma. I believe that the inference is warranted that there is no necessary connection between the two conditions. The invariable cause of the nervous symptoms of diabetes, if there be one cause, is unknown.

When the patient was before you I did not go into the cause of these symptoms, as we had not the time, but I referred to a blow upon the head received in early childhood. As he had been well for many years afterwards, I advised you not to attach much importance to this. Have

we, then, a more direct explanation of the cerebral disease? Here we find softening of the crus cerebri, of the pons, and of the floor of the fourth ventricle,—in other words, of those parts of the brain which when diseased are known to be associated with diabetes mellitus, and in the neighborhood where, in animals, puncture will give rise to glycosuria.

I believe that in the present case these lesions were due to syphilis and had no connection with the old head-injury. They are recent, there is decided atheroma of the arteries, and diffuse lesions in the meninges, besides the softening in the crus and pons. Microscopic examination shows the deposits to be syphilitic, and some are decidedly gummatous in character. I regret that the history of this case is so defective, but we have learned from the friends of the patient that he had not been in usual health for nearly a year; he often spoke of vertigo, and complained of rheumatic muscular pains, which were probably syphilitic. He did not, however, particularly complain of headache, although he had been more or less subject to headache all his life. We could not find any evidence that there had been any increase in his headache recently, nor is there a history of any disturbance of special sense. He had lost flesh rapidly of late, and this was associated with increase in cough. Although during life the diagnosis of cerebral syphilis was a pretty vague one, it was fully confirmed by the autopsy.

Another question which is of considerable interest here is, Are the lesions in the lungs tubercular or syphilitic? This will bear careful study. An examination of the lungs failed to show the presence of the bacilli of tubercle, yet the other features were so characteristic, so like ordinary tubercular lesions, that I will pronounce the case one of acute phthisis complicating diabetes terminating in diabetic coma. The latency of the symptoms may have been due to the slow progress of the syphilitic deposit, but the specimens before you show it to be undoubtedly a case of cerebral syphilis.

ANTIPYRIN FOR HEADACHE. — Various kinds of headache were promptly relieved at their onset by fifteen-grain doses of antipyrin, in the hands of Dr. John Blake White, of New York.

ORIGINAL COMMUNICATIONS.

A REPORT ON RECENT PROGRESS IN NERVOUS AND MENTAL DISEASES.

BY JAMES HENDRIE LLOYD, A.M., M.D.,
Instructor in Electro-Therapeutics in the University of Pennsylvania.

MULTIPLE NEURITIS.

DR. W. R. GOWERS, in his recent work ("A Manual of Diseases of the Nervous System"), gives a very clear description of this disease, which is now attracting so much attention.

He thinks that the "discovery" of multiple neuritis is one of the most important steps in the recent advance of neurology. The morbid change may be interstitial (between the fibres), or parenchymatous (degenerative change of the fibre itself), or both. He differentiates five forms of the disease. (1) Diphtheritic neuritis: a parenchymatous degeneration of the nerves, associated, however, with disease of other parts. (2) Tabetic neuritis: the slow chronic changes in nerve-trunks which occur in locomotor ataxia, and which may possibly not be inflammatory. (3) Leprous neuritis: the slow interstitial overgrowth of connective tissue which occurs in anæsthetic leprosy. (4) Endemic neuritis, as in the Japanese disease called kakké (and the more familiar beri-beri?). (5) Under this head he places the "other forms of multiple neuritis," which, indeed, constitute the disease to which the name is usually restricted. Gowers finds the disease most common in females, which is unexpected when he states that by far the most common cause of it is chronic alcoholism. In fact, he uses the terms "alcoholic paralysis" and "multiple neuritis" as almost identical." Among other causes, however, which he admits to be sometimes operative are cold, fatigue, rheumatism, phthisis, septicæmia, and exhausting diseases.

The pathology may consist either in parenchymatous or interstitial changes in the nerve-trunks, but in severe cases probably in both. He insists that the fibres are always damaged; but in some cases the connective tissue presents little change. As the trunks are traced upward, the evidence of inflammatory changes becomes slighter, and in all forms the anterior roots are usually normal. The nerves in

the limbs alone suffer in the majority of cases, and the affection is bilateral. The nerves supplying the extensor muscles of the hand and foot are especially liable to attack. Very rarely the phrenic, pneumogastric, facial, and hypoglossal have been inflamed, the other cranial nerves escaping. The muscles usually degenerate, as in simple forms of neuritis. The cord is usually normal. The symptoms are the same as follow inflammation of a single nerve, differing only in their wide range; they are especially motor palsy and sensory irritation. The motor palsy, as said above, is apt to be most pronounced in the musculo-spiral and anterior tibial nerves. [It is rather unfortunate that Gowers insists upon saying that the extensors *flex* the foot. The anterior tibial nerve supplies *extensor* muscles, which, by perfect analogy with the extensors in the arm, *extend* the foot. Hence in the paralysis resulting from multiple neuritis we have both wrist-drop and foot-drop. This solecism occurs through the whole chapter and book.] The symptoms are apt to set in acutely, and to be accompanied by rigors and fever. The sensory symptoms come first as vague "pins and needles sensations" in fingers and toes, preceded perhaps by rheumatoid pains. These pains increase until finally the nerve-trunks become tender on pressure, and superficial nerves, as the ulnar, may be felt to be distinctly swollen. The muscles also become very sensitive to pressure. Motor palsy supervenes, and resembles in the arms lead palsy, with the important distinction that the supinator longus muscle is apt to be involved, as it is not in plumbism. In severe cases the flexors of the wrist and ankle (hand and foot) also become involved, as do also the muscles moving the elbow-, knee-, shoulder-, and hip-joints. Electrodiagnosis is important. The nerve-trunks lose their electrical excitability [probably more completely than in some forms of anterior poliomyelitis], and the muscles put on the reactions of degeneration. Gowers calls attention to a distinct incoordination of movement, which it is important to distinguish from locomotor ataxia. The sensory phenomena are, briefly, hyperæsthesia of the extremities, especially of the palms and soles; anæsthesia along the radial side of the forearms and outer side of the leg in particular, sometimes associated with pain (*anæsthesia dolorosa?*). Reflex action is *always* lost. Trophic changes and œdema have been observed. The duration of the disease varies, but at best it is apt to extend over several months. In very severe cases death has occurred from failure of the muscles of respiration, especially the diaphragm. An important complication is mental impairment, often with delusions, particularly in the alcoholic cases.

The author does not make any novel recommendations by way of treatment. He relies upon rest, hot fomentations, counter-irritation, and the galvanic current. The article is chiefly valuable for its clear-cut, lucid description of the disease, in the author's well-known style; which description is especially welcome now, when so many diverse affections are being hastily grouped under this head in the modern eagerness for clinical novelties.

INFANTILE CEREBRAL PARALYSIS.

Dr. R. Norris Wolfenden, in the *Practitioner* for September, 1886, describes four cases of this affection. The disease has also been called spastic cerebral hemiplegia, and, again, *poliencephalitis acuta.* These names, among them, manage to describe something of the disease. The last, as indicating the pathology and being analogous to *poliomyelitis*, is on some accounts the best, were it not too technical and pedantic. One of these cases was briefly as follows. A boy of ten months was attacked with a series of convulsions, followed by paralysis of the left arm and leg. For six months the leg and arm were spastic; then they relaxed, leaving permanent weakness. Epileptiform attacks continue at intervals of about twice a week. Intelligence had been much impaired, so that at eight years he could not be taught to read. Weakness of the arm and leg continued, and the fingers were subject to slight athetotic movements. The tendon-reflexes of this side were exaggerated. There were no reactions of degeneration.

The disease is distinguished from *spinal* paralysis by the affections of the intellect, speech, special senses (sometimes), and the absence of impaired sensibility. In the spinal form also there is atrophy and coldness, with progressive reactions of degeneration, while the spastic condition is not an early and characteristic sign. Club-foot deformities are more constant and

persistent in the latter. The cerebral form may be said to occur more as a hemiplegic and epileptic *type*. The disease has followed dentition and the eruptive fevers, but in many cases the cause cannot be determined. It is an affection of early infancy. The pathology is somewhat obscure; but the indications are that the motor cortex of the brain is the seat of a circumscribed inflammatory process or some other form of degeneration.

[We no doubt have in these accidents the cause sometimes of acquired idiocy. The resemblance of the cases of Dr. Wolfenden to the *focal* epilepsy of Hughlings-Jackson seems to be marked, although the writer does not dwell upon it. The rapid and permanent injury to the brain is what we would expect in very young children. It seems strange that the descending degeneration along the motor tract of the spinal cord, as described by Charcot in adults, with continued contractions in the affected limbs, is not more noticeable in these reported cases. Exaggerated reflexes are part of this symptom-group. These cases are to be distinguished from that other class of imbeciles which depends upon a congenital abnormality or arrest of development. These latter cases usually show some tendency in the fissures and convolutions of the brain to a reversion to a lower type of cerebrum. Dr. Francis Dercum exhibited a series of such brains at the last meeting of the Philadelphia Neurological Society, all taken from epileptic dements, and explained a theory for the epilepsy based upon the loss in such brains of their static equilibrium because of unequal development of cortical areas.]

MUSCULAR ATROPHY IN HYSTERICAL PARALYSIS.

Dr. J. Babinski has a lengthy article on this subject, commencing in the July number of the *Archives de Neurologie*, in which the writer states that his treatise is designed to show that trophic disorders, especially muscular atrophy, can depend on hysteria and can be observed in hysterical paralysis. He says that observations at the Salpêtrière under M. Charcot have established this point. He gives cases in great detail, to only one of which we can refer at present. This was a young man of 21, of marked hysterical characteristics, who was suddenly taken with a left brachial monoplegia, with complete anæsthesia. He was unconscious for many hours. For more than two months the paralysis persisted, with alternate flaccidity and contractions, and was accompanied by a quite pronounced amyotrophy. Other symptoms were a slight paresis of the left leg; various hysterical attacks caused by pressure in certain regions; hemianæsthesia; transitory hysterical mutism; occasional retention of urine. The monoplegia disappeared under massage, with "flagellation" in the right temporo-parietal region. The amyotrophy disappeared upon the return of the movements. Babinski makes the differential diagnosis between this affection and an organic lesion of the motor cortex in the arm-centre, and slightly in the leg-centre, which the case certainly strongly resembles. The resemblance is further sustained by the contracture of the affected arm, as well as its wasting, both of which might have been caused by a descending degeneration along the motor paths from such a lesion in the cortex, as has been shown by Charcot and others. He argues that the alternating character of the rigidity and flaccidity is against the view of a secondary descending degeneration, as is also the early appearance of the contracture. The convulsive attacks were proved to be hysterical by the *globus hystericus*, by the fact that they could be produced by pressure on certain hysterogenic zones, by opisthotonos, and by the sudden return to consciousness. Again, the abolition of sensation is much greater in this case than would occur in a cortical organic lesion. The affected muscles did not show any fibrillary contractions, and the only electrical change noted was a diminished contractility without modal change or the reactions of degeneration. The muscles manifestly affected were the deltoid, great pectoral, shoulder muscles, biceps, and triceps. By actual measurement the paralyzed arm was about three centimetres less than its fellow.

[Wasting of muscles, with diminished electro-contractility, has been noted before in hysterical affections and attributed to disuse merely; but the interest which attaches to M. Babinski's case is that it occurred very quickly after the paralysis, so as to suggest almost an active process, and resembled, because of its marked character, the amyotrophy of an organic lesion.]

CAPILLARY EMBOLISM AND CHOREA.

Dr. Angel Money publishes in the *British*

Medical Journal for July 17, 1886, the results of his experimental studies of chorea. His experiments were made upon monkeys by injecting preparations of starch into the carotid arteries. The principal result obtained was hemiplegia, and not chorea. Dr. Money's conclusions are as follows, and from them it will be seen that he is by no means one-ideaed about either the nature or the seat of the lesion:

1. Human chorea is generally and mainly of cerebral origin, though a few cases may be of purely spinal source.

2. The commonest lesion causing chorea is a "rheumatic" affection of the circumvascular connective tissues of the motor apparatus of the brain and cord.

3. Embolism may be a cause of chorea in rare instances.

4. Chorea may be set up by "fright," when the lesion is probably a molecular disturbance of the cerebro-spinal motor apparatus.

THE CONNECTION BETWEEN EMPYEMA AND HEMIPLEGIA.

The details of a case are given in abstract in the *Practitioner* from M. Barbez, who reports it in the *Revue de Médecine* for June, 1886, in which five weeks after the evacuation of a highly-offensive empyema the patient became suddenly paralyzed in the right arm, with aphasia, and continued for more than two months in this condition, with mild delirium. There were some spasms of the affected arm.

Especial attention is attracted to the case by the explanation which is given of the connection between the two conditions. M. Luys considered it a case of limited left lateral meningitis. But M. Barbez classes it among so-called *reflex* hemiplegias, cases of which have been reported by several writers. The explanations seem very far-fetched to us. As the patient had a good ground-work for pyæmia, we would rather suppose that his brain-trouble was of septic origin, probably embolic.

CASTRATION IN MENTAL AND NERVOUS DISEASES.

In the *American Journal of the Medical Sciences* for October, 1886, a "symposium" is given under the above heading, contributed by Sir Spencer Wells, Dr. A. Hegar, and Dr. R. Battey. It is the most important series of opinions on this subject, as affecting the neurologist, which has appeared. The student of mental and nervous diseases had regarded as exploded the old theory that the womb, or its appendages, was the seat in any sense of the grave neuroses and psychoses. His new faith, however, was threatened, and perhaps a little shaken, by the zeal of the gynæcologists, who began to report that they cured hysteria, and even insanity, by spaying women. The authoritative opinions now expressed in this "symposium" by three of the most eminent specialists will give the neurologist an opportunity to form anew his own judgment on the subject; and we doubt if he materially recasts it. Our limited space permits us to do little more than mention the conclusions of the writers.

The paper of Wells is the broadest, most critical and entertaining, of the three. "The oöphorectomists of civilization," he tells us, "touch hands with the aboriginal spayers of New Zealand." We are not concerned, of course, with the ablation of normal ovaries in cases of uterine fibroids with uncontrollable hemorrhages, nor in malformations of the genital organs and obstructions of the vagina,—in some of which cases this eminent surgeon cautiously endorses the operation, — nor hardly in uncontrollable neuralgia, if it be *really proved* to be ovarian (in which case one enthusiast would pull out the gland as he would a bad tooth); but for pure nervous and mental diseases we put great confidence in the following conclusions of Sir Spencer Wells: "That in nearly all cases of nervous excitement and madness it is inadmissible; that in nymphomania and mental diseases it is, to say the least, unjustifiable."

In the papers of Hegar and Battey, who were original champions of the operation, the reader will be apt to expect more of the logic of the special pleader; but, while he does find this, he will be constrained to admit that the papers are in a sense conservative, and, by implication, not a little condemnatory of many who have undertaken this grave operation. The fault with Hegar's paper, for the practical neurological mind, is its abstruseness. He works out his principles with a minuteness and prolixity which are quite characteristic, but leaves the reader in doubt as to who will make these nice distinctions and apply these principles with precision. He does not give his conclusions in abstract, so as to be readily quoted, but the trend of the

reasoning is that, if a distinct causal relation can be established between the ovaries and a mental or nervous disease, it is reasonable and justifiable to cut them out. This as a broad principle might be difficult to combat, but it leaves the operator in each individual case as the sole guarantee that such a relationship *did* exist,—a diagnostic pre-eminence which all neurologists will certainly not yield to all who do this operation.

Dr. Battey begins his paper with a remarkable plea (as lawyers say) of confession and avoidance. He says he was mistaken in his early cases when he called the operation "*normal* ovariotomy:" that the ovaries and tubes removed have really been diseased. The diseases are small cysts and "fibrous degeneration" of the stroma. This seems as though meant to give the operation more plausibility; but the force of it is weakened by a quotation from Emmet, in this very article, who says that in hundreds of post-mortems he has learned "that what seemed to be a perfectly healthy ovary was a condition seldom found after death in any woman over twenty-five years of age." Dr. Battey castrates for oöphoro-mania, oöphoro-epilepsy, and oöphoralgia. The majority of alienists will probably deny point-blank the very existence of this first disease. It is doubtless meant to specify the severer forms of hysteria, just as the second class signifies the convulsions of that mystic disease. The fact that *all* the pseudo-epileptics (nine in all) are cured suggests strongly the effect of mental impression; while the fact that only one of his seven cases of mania is cured suggests equally that he has operated upon some genuine cases of maniacal insanity.

The following is Battey's table, all the cases having stood at least two years:

	Cured.	Improved.	Not Improved.	Total.
Oöphoro-mania.....	1	4	2	7
Oöphoro-epilepsy	9	0	0	9
Oöphoralgia.....	13	3	4	20
Total.....	23	7	6	36

It will be seen that ovarian neuralgia, the least serious disease of the list, gives the second-best results. The article closes with quotations from many well-known operators in America,—some of them very general, a few hopeful in their limited experience, all cautious, and one—Dr. Emmet, like Sir Spencer Wells—positively discouraging.

A more hopeful field for the surgeon in brain-disorders is mapped out in the following article.

BRAIN-SURGERY.

Mr. Victor Horsley read an elaborate paper recently on the surgery of the cortex before the British Medical Association, which has been published in the *British Medical Journal* for October 9, 1886. He treats especially of the surgical details necessary to the immediate operation, of which it is sufficient to say that strict antisepsis is inculcated and the most exact directions given about the incision, hemorrhage, hernia cerebri, and subsequent treatment. The student of brain-diseases will be especially interested in the cases of Horsley, their successful diagnosis, and the light which they throw upon the functional topography of the cortex.

Case I. was a young man, aged 22, with traumatic epilepsy dating back fifteen years. He had as many as *three thousand* fits a fortnight. He had a scar with absence of bone directly over the centre of the upper third of the ascending frontal convolution. His fit corresponded exactly to such as are produced from a focus of discharge in this locality,—*i.e.*, the parts affected were in the order of lower limb, upper limb, face and neck of the opposite side, the movement being first extension, then confusion, then flexion. A mass of fibrous tissue was removed beneath the scar. Temporary paralysis of the affected arm, with some loss of *tactile sensibility* and muscular sense, followed, but gradually disappeared. Up to the time of the report the patient had had no fits.

Case II. is a remarkable instance of successful diagnosis. An irritative lesion (which proved to be a tumor) was foretold in the ascending frontal and parietal convolutions, at the junction of their lower and middle thirds. This location was suggested by the spasmodic opposition of the thumb and forefinger which ushered in each fit. The tumor was successfully removed. It was followed by *temporary* paralysis of the affected members, also some *hemianæsthesia*. A complete cessation of fits was reported to date.

Case III. was an inveterate epileptic, having fits in batches of three or four every three weeks. The condition dated

back to an injury probably nineteen years before. This man had hemianæsthesia. The diagnosis was an irritative lesion in the posterior third of the superior frontal convolution. Depressed bone and scar-tissue were found, as predicted, and removed. The following are Horsley's deductions:

1. Temporary paralysis of motion and muscular sense may follow ligature of the vessels supplying that part of the motor area in which the lost movements are represented.

2. Temporary paralysis of sensation and movement of the so-called hysterical or functional type may follow operations upon the motor area in man.

3. These cases suggest the possibility of the muscular sense being represented in the excito-motor area.

It is interesting to note that the hemianæsthesia which existed in Case III. was dispelled by a strong faradic current to the region of the scar, but that the fits were not affected by it.

It is impossible to do perfect justice in an abstract to this very important and original paper of Mr. Horsley upon the gross physiology, pathology, and surgery of the brain. His cases supplement that of Bennet and Godlee in London and the successful one of Mills and White in Philadelphia.

TRANCE-CASES IN INEBRIETY.

Under this head in the *Journal of Nervous and Mental Diseases*, September–October, 1886, Dr. T. D. Crothers, of Hartford, Connecticut, describes spells of sudden loss of consciousness in inebriates somewhat similar to the "blanks" of epilepsy. They vary as in epilepsy, and may be partial or complete. They are sometimes of long duration (three hours). "Thus, an inebriate suddenly changes in conduct and language without any cause or reason, and without the usual symptoms of intoxication; or he follows an accustomed line of action in such an automatic and mechanical way as to excite attention and yet not be intoxicated. Afterwards he claims not to have remembered these periods, and his conduct and language sustain his statement."

The author of the paper thinks that great importance attaches to these trance-like spells as affecting the question of responsibility. He gives a number of interesting cases in support of his belief in this condition. "Prominent crimes and acts committed under strange, unusual circumstances by inebriates may furnish good evidence of these trance-states." Absence of motive becomes an important consideration in connection with any crime committed in this state. In the trance (which is to be distinguished from the excitement or stupor of intoxication) the individual *appears* to know exactly what he is doing, but afterwards has no memory of it whatever. These *blanks* usually occur during prolonged drinking-bouts, in which the man keeps himself constantly *full* without becoming overwhelmed with his liquor. As illustrations, "a hotel-clerk will, after periods of excess of drink, wake up in a Turkish bath, and have no idea how he came there. A farmer has found himself working on the farm, and the last event he could recall would be at a distant bar-room." These trances may occur at the beginning or during or after the alcoholic poisoning. A merchant "loses all recollection of what takes place; has no idea but that he has been asleep; and cannot realize that some days have passed in which he has been about with apparent sanity and judgment."

Dr. Crothers has a poor opinion of the memory of a confirmed inebriate, and thinks he is a most incompetent witness of any facts concerning himself or surroundings. In a recent murder trial, the prisoner, an inebriate who committed the crime while in one of these trance-states, was told at the police-station by an officer some details of the act, which he afterwards recited as events he could remember. On this he was convicted. It was ascertained afterwards that these details were false and unsupported by the facts. They were the views of the officer, and the prisoner did not recognize their origin or inconsistency. Another inebriate confused his own confession with that of a fellow-burglar confined in the same cell. This *impressibility* by the immediate surroundings, with automatic response to external impressions, and loss of memory appear to be the distinctive features of this interesting state. The author expresses his belief that responsibility in these cases can be determined only by careful study of each case, and not by any preconceived theory of responsibility in disease.

[The law is slow to allow a man to plead his own minor crimes in defence of his major ones: hence drunkenness has not been considered an excuse for murder. This may or may not be philosophical and humane; but it has been supported by the general sense of mankind. The usual exceptions to this rule seem to be in cases of chronic alcoholism, wherein the man may be said to have established a permanent psychosis, such as the drunkard's delusion of marital infidelity. Dr. Crothers's instances of *trance* in chronic inebriety would probably come under this head of established brain-impairment. The condition, if well determined, would certainly raise an interesting question of responsibility, which it might be easier for an alienist to settle to his own satisfaction than to prove to a judge and jury. Ray reports a very interesting case of this kind.]

THE CLASSIFICATION OF MENTAL DISEASES.

On the 8th of September past, a conference representing various distinguished scientific bodies of the United States and Canada, and eminent alienists and publicists, was held at Saratoga, New York, for the purpose of co-operating with an International Committee appointed at Antwerp last year under the auspices of the Belgian Society of Mental Medicine. The object was to recommend to this International Committee a basis for classification of mental diseases, in the hope of securing a uniform basis in all countries of the civilized world. The following plan of classification was adopted:

1. Mania: acute, chronic, recurrent, puerperal.
2. Melancholia: acute, chronic, recurrent, puerperal.
3. Primary delusional insanity (monomania).
4. Dementia: primary, secondary, senile, organic (tumors, hemorrhages, etc.).
5. General paralysis of the insane.
6. Epilepsy.
7. Toxic insanity (alcoholism, morphinism, etc.).
8. Congenital mental deficiency (idiocy, imbecility, cretinism).

[It will be seen that this classification is remarkably free from the elaborate differentiations which are now adopted by some writers. It looks like a reversion to the simplicity of a former and, it was supposed, more ignorant generation. The truth is that while the clinical study of insanity has advanced and been very prolific of a useful and instructive literature, our knowledge of the *essential* functions and pathology of the cerebral masses is not greatly more advanced than it was with the fathers; and without more of such intimate knowledge (unbiassed by speculation and opinion) the very foundation for a perfectly acceptable classification does not exist.]

FACIAL SPASM AND TIC-DOULOUREUX FOR WHICH NEURECTOMY AND NEURO-TENSION WERE EMPLOYED.

Read at the Philadelphia Neurological Society, December 27, 1886,

BY GUY HINSDALE, M.D.

I HAVE the pleasure of asking your attention to the records of two cases of persistent trifacial neuralgia and also a case of painless facial spasm. The two former were under the care of Dr. S. Weir Mitchell at the Infirmary for Nervous Diseases, and the last under the care of Dr. W. Sinkler, by whose permission they are brought before this Society.

The cases are of interest from the fact that the first was treated by medicines pushed to an extreme limit; the second, failing to improve under medicines, was treated by exsection of the infraorbital nerve; while the last was treated by stretching the facial nerve.

The cases are not reported because of any supposed rarity, or because they are in any way particularly remarkable; but merely to show what is the practice of the hospital, and to invite an interchange of views as to the relative merits of the treatments adopted.

Mrs. H., suffering with neuralgia of the right side of the face, entered the Infirmary for Nervous Diseases November 9, 1885. She is 62 years old, was born in New Jersey, and has always lived there. She considers her home dry and healthy and free from malaria. Her father died with phthisis. The patient herself has never had malaria or chills and fever, but had an attack of pleurisy fifteen years ago, associated with a severe cough. This has been her only severe illness. She has been married forty-two years, and has had fourteen children, of whom two only are living. Eighteen years ago she experienced a severe shock in the loss of six children from diphtheria within a period of four weeks: she had previously lost others in their infancy.

Twenty years ago the patient began to have twinges of pain in the lower jaw. Four or five years ago she suffered from attacks of neuralgia of the right side of the face two or three times a year: these attacks lasted from one to three months. In 1884 she had four or five attacks, one of which lasted two months; though quite weak, she was not confined to her bed at any time. Fever sometimes accompanied the attacks, without any chill, but with a cold sweat when the pain was very severe.

A year or two ago the pain occurred at any time during the day, but passed away at evening, upon retiring and remaining quiet. In April, 1885, the pain began to be worse at night, but it cannot be said that any special hour was observed. Cold air, eating, or drinking very hot drinks, motion in bed, bad news, mental trouble, aggravated the pain. Rest, peppermint-essence dropped on the tongue, sweating the face with hot bricks dampened with whiskey and wrapped in cloth, did for a time relieve the pain.

The treatment adopted consisted of rest in bed, good feeding, and the use of an ascending galvanic current. This was applied to the right side of the tip of the tongue and to the right side of the lower jaw for fifteen minutes, morning and evening. This was the chief locality of pain. Cod-liver oil, ʒiv, and tinct. aconiti rad. were given after meals. The aconite was gradually increased in quantity until, on the nineteenth day, she was taking seventeen drops four times a day. Elixir of iron, quinine, and strychnia, one teaspoonful thrice daily, was then added. The early doses of aconite, of two and three drops each, produced some tingling of the fingers and tongue, with numbness of the right arm and hand; the larger doses did not produce any more pronounced symptoms. The pulse varied in frequency from 67 to 82 per minute. Hydrochlorate of cocaine in four-per-cent. solution was applied two or three times a day to the painful spot on the right side of the extremity of the tongue; this gave relief for about twenty or thirty minutes. Failing to control the pain notwithstanding this persistent use of aconite, on December 1 fluid extract of gelsemium was used; four drops were given thrice daily, and the dose gradually increased until the physiological effect was produced. Hunyadi water was given occasionally, and massage of the spine was adopted. On the following morning a blister was applied to the right temporal and zygomatic region; a cold-water dressing containing half a grain of morphine was used. The blister had caused considerable local irritation by evening, and the pain in the face and tongue was relieved; the pain, however, recurred the next day, with dull aching in the forehead and across the eyes.

Lunar caustic was applied to the right side of the tip of the tongue on December 4; the area cauterized was about half an inch square. Electricity was suspended for three days. Subsequently applications of nitric acid were made to the tongue.

Swimming of the forehead, dimness of vision, and drowsiness accompanied the increasing doses of gelsemium. The dose of gelsemium was increased for twenty days, until the patient took thirty-six drops of the fluid extract three times a day; there were then dizziness, headache, some drooping of the eyelids, but no pronounced symptoms or apparent benefit from the medication.

I have prepared a chart from the careful daily records taken by Miss Kenealy, the chief nurse of the Training School, showing for each day the treatment, the pulse, respiration and temperature, and subjective symptoms.

At the end of seven weeks the patient was discharged, although still suffering at intervals from pain in her tongue. The facial pain was very much less than when she applied for treatment. The use of nitric acid on the painful spot in the tongue was advised.

At the end of six months the patient was still suffering with neuralgia, but not so severely as at first.

Mrs. E. H. H., æt. 64. No hereditary nervous disease. She was delicate in early life, and as a child had chills and fever for three years, but never had any serious illness. Thirty years ago she began to have pain in the infraorbital, and then in the supraorbital, region, darting and of intermittent character. It was serious enough to confine her to bed. The attacks were influenced by weather and exposure. Sometimes attacks came on every few days; sometimes not once in three or four months. Exposure to draughts, to cold, or to wind would bring them on. Warmth would relieve the pain. Liniments failed; warmth always gave the most relief. Duration of attacks one to seven days, or even a month. For seventeen years she had noticed a singular sensation in the right nostril, as though pierced by a dozen needles. Pain extended to the cheek and under the eye. The patient for four years had a severe attack lasting the whole month of February. It would take an entire month to recover from its effects.

November 21, 1885, the pain was constant and more or less severe, both diurnal and nocturnal, and she was kept awake a great deal at night. Teeth had been extracted from both jaws before applying for treatment.

A general tonic treatment, consisting of massage, lactate of iron, cod-liver oil, and malt, was adopted, and galvanism was applied gently to the side of the face. Blister-

ing, morphine, quinine, arseniate of iron, and bromide of lithium were applied in succession, without relief.

Finally, the infraorbital nerve was exsected by Drs. Hunt and Morton, a small portion of the floor of the orbit being also removed. The patient suffered a good deal of pain in the same spot as before; this, however, subsided to a certain extent, and two weeks after the operation she returned to her home in Maryland. While not altogether free from neuralgic pain, she considered herself much more comfortable than before and greatly improved in general health. Nine months later she was reported to be in good health, with little or no neuralgia.

In a case of painless spasm of the face, Dr. W. W. Keen has recently operated on a patient at the request of Dr. Wharton Sinkler. The patient had twice been paralyzed. Five years ago the right eyelids began to twitch, and in six months the whole face and the platysma were incessantly in spasm, which was increased by mental or muscular effort; later this was accompanied with constant pain. In June, 1884, the right infraorbital nerve had been resected, with partial relief for only six weeks. Not long after this the twitching extended to the right side of the body and to the leg.

April 2, 1886, Dr. Keen laid bare the trunk of the nerve, using an electric current to facilitate its discovery. The nerve was then stretched; the force used was just short of enough to lift the head. Total paralysis of the face followed, with relief not only of the spasm of the face and neck, but also of that of the side and leg.

Stretching of the facial nerve for cramp had been performed by Baum and Schüssler, in 1878, Eulenberg, Godlee, Hahn, and others.

In Eulenberg's case, stretching the nerve was resorted to after a neurotomy of the supraorbital had failed; a tolerably severe paralysis resulted, lasting several weeks, but finally disappeared. In Godlee's case, twenty-eight months after the stretching the favorable result remained. In Hahn's case there were spasms over the whole right side of the face; after the operation, which did not induce any paralysis, there was only partial benefit. Two years after the operation the cramps persisted.

In 1880 Langenbeck stretched the temporo-orbital division of the left facial nerve and also a branch going to the zygomatic muscles. After twelve days the eye remained wide open, paralyzed; the angle of the mouth drooped. Two months later paresis of the left side of the face was still apparent; return of spasm. After four months the spasm was as severe as ever, and the paresis was apparent. The patient thought the paralysis the lesser evil of the two.

In a case of Godlee's in which there was painful spasm of both sides of the face, the left facial was stretched; paralysis followed. Four months later the right nerve was stretched. Several months after this the paralysis had disappeared, and the condition was as bad as before the operations.

In Putnam's two cases the results were not encouraging.

In a case of Southam's in 1881, the paralysis vanished in sixteen weeks; two and a half years later the good result was still apparent.

Dr. Zesa's summary of nineteen cases gave permanent good results in three, doubtful in two, considerable improvement in four, failure in ten. In ten cases temporary benefit followed the operation.

TRANSLATIONS.

Septicæmia of Rabbits.—At a recent meeting of the Paris Biological Society, M. G. Daremberg made the following statement concerning septicæmia in rabbits. This disease is produced by the inoculation of tuberculous matter (lungs, lymphatic ganglia) taken from dead bodies in the heat of summer, when there is slight putrefaction. Rabbits thus inoculated die after an interval of twenty-four to forty hours. Septicæmia is inoculable by means of subcutaneous, peritoneal, or intravenous injections, and also by trephining. Some hours before death the animal loses all desire for food, is in a panting condition, and is depressed; it is attacked by diarrhœa and convulsions, it cries out and drags itself painfully along between the convulsions, is paralyzed in one or more of its limbs; sputum mixed with blood issues from the nostrils and mouth. The animal is rarely struck down without exhibiting the preceding symptoms.

Necropsy reveals a sero-sanguineous infiltration in the areolar and connective tissues, round about the spot where the

inoculation was practised; ecchymoses; slight capillary hemorrhage on the surface of the intestines; areas of pulmonary apoplexy; hepatic infarctions; the spleen enlarged and black; occasionally serous or fibrinous effusions in the peritoneum and pleura; large clots dispersed about, but more especially in the sinuses of the dura mater and pia mater; occasionally slight meningeal hemorrhage, or in some cases encephalic and medullary meningitis.

These clinical and anatomo-pathological symptoms are in accordance with those described by Koch in cases of experimental septicæmia of rabbits; with those described by M. Charrin in cases of septicæmia produced through deteriorated blood in charbon; and with those by M. Pasteur in cases of disease inoculated by means of the microbe of saliva.

M. Daremberg states that the spinal marrow from his rabbits, whether fresh or dried during twenty days, causes death in rabbits at the end of twenty-four to forty hours. From the twentieth to the twenty-fifth day of desiccation the toxic properties diminish in strength, and the medulla only kills the animal after three or five days have elapsed. When the twenty-fifth day of desiccation is reached, the medulla does not generally kill the animals, but they are ill for two or three days (loss of appetite, depression). It was observed that in two cases the caudal extremity of the spinal marrow, after only eighteen days of desiccation, did not kill the animals. After ten transmissions from one rabbit to another, the medulla kills animals in five hours; at this juncture the disease becomes epidemic and kills nearly all the animals in close vicinity. A medulla dried in oxygen kills rabbits twice as rapidly as a medulla dried in the open air. Air at 55° Cent. (131° Fahr.), nitrogen, carbonic acid, and mercury vapors at 15° Cent., and at 55° Cent. (131° Fahr.), the vapor of osmic and cyanhydric acids, of pyridine, of iodine, of ethyl or amyl, of benzine, of turpentine, of sulphur, of carbon, of thymol, paraldehyde, methylated spirits, acetic ether, do not diminish the toxic properties of the medulla. Iodoform, phenol, and ammonia vapors delay the death of the animal one or two days. Vapors of chloral, chloroform, aldehyde, amylic alcohol, sulphuric ether, sulphurous acid, and sulphuric anhydride destroy all toxic influence in the medullas when they are allowed to dry in an atmosphere impregnated with these substances during four or five days. The same result is obtained by means of vapors of nitrous or of those of chlorhydric acid, which reduce the medullas to a pulp.

The blood and all the organs of animals that have died from this infectious disease contain an ovoid micrococcus, which may be cultivated in veal-broth and in gelatin. The latter is not liquefied. The micrococci are occasionally dispersed in small rows or in zoögleic clusters, rarely in twos or fours. But these conditions are not constant, and the successive cultivations in broth and gelatin present sometimes one aspect, sometimes another, and often a variety of aspects; the toxic action of this micro-organism is always the same, and is equal to the fresh medullas. These cultivations preserve their virulence at 55° Cent. (131° Fahr.). Towards the seventeenth day they become less toxic, and only cause death in four or five days, and in some cases are inert.

The second cultivations are less virulent than the first; either coagulates milk. These properties prove the analogy between this micrococcus and that described by M. Pasteur, of which the first cultivations die in fifteen days, and the successive ones gradually fall away. They differ from the properties described by M. Charrin, of which the cultivations die at 45° Cent. (113° Fahr.), and of which the second cultivations are as virulent as the first. M. Daremberg has attempted the Pasteur method of successive inoculation, but without positive results. An absolute method of protective inoculation for septicæmia has yet to be discovered.

Residue of the Ferments. — MM. Gayon and Dupetit, in a communication to the Academy of Sciences, point out a new means of preventing secondary fermentation in industrial alcoholic fermentations. It is well known that such products are rarely pure. It has often been tried to prevent the development of ferments, other than that of yeast, by adding to the must certain antiseptic substances. The addition of tannin was found to prevent the development of these secondary ferments, with the exception of the mycoderma aceti. On the other hand, the salts of bismuth completely prevent the latter variety of fermentation.

EDITORIAL.

THE COSMOPOLITAN CHARACTER OF MODERN SURGERY.

THE Second French Congress of Surgery was opened with a masterly address by the President, Professor Ollier, of Lyons, in which, after felicitating his hearers upon the institution and prospects of the Congress, he urged upon them the importance of looking beyond the borders of their own country for instruction wherever it could be gained, and not resting in a self-complacent exclusiveness.

"Nothing," he says, "which occurs in the surgical world ought to be foreign to us. Patriotism does not consist in admiring one's self and closing the eyes to the advances of one's rivals; but in becoming informed in regard to these advances, in utilizing them, and in attempting to surpass them." This recommendation, however, is not so much needed now as it once was, as indeed he admits. The affected superiority to other nations which once led French scientific men to ignore them and their work is, happily, disappearing, and France now shows a creditable appreciation of what is going on elsewhere, getting and giving with the freedom which should characterize the republic of letters. Examples of this are to be seen in the adoption—as yet too imperfect—of the principles of asepsis in surgery, which have now gained a fair foothold in France; also in the promulgation abroad of such doctrines as those of Ollier himself in regard to the nature and treatment of diseases of the bones, or the more recent revival of the suprapubic operation of lithotomy in England, which is directly attributable to what Sir Henry Thompson very recently learned from Professor Guyon in Paris.

Ollier touched upon other interesting topics, such as the improvement of hospital facilities in France, the improvement in their outfit and *personnel.* In regard to the latter point he made some remarks which show that he has some very decided notions as to the proper way in which to increase the success and reputation of medical centres. The rank of surgery in any country, he says, is determined chiefly by two things: the worth of those who fill its ranks and the opportunity afforded them to accomplish what they are fitted for. In France he finds that there is at present more ability than opportunity. Capable men either have no fair chance to work, or their talents are even smothered by public institutions. At present, he says, there is a veritable plethora of talented young men for whom it is almost impossible to provide opportunities for work. One might suppose that he himself was one of these young men, so impassionedly does he plead that they shall be given the opportunity to act for themselves, to exercise their talents. He depicts their patience, then their weariness in waiting, and, finally, the diminished zeal with which their work is done when at length the coveted opportunity is secured.

This state of affairs involves a great waste of power and a serious detriment to surgery in France. It does not exist everywhere, however. Even in France there are cities in which the young surgeons are carefully and successfully fostered, and in which these have come to shed lustre upon the institutions with which they were connected. Lyons, we might say, and Ollier in Lyons, could not well be mentioned as examples by the speaker; but bright examples they are. Likewise—as the speaker did say—the large number of small universities in Germany has favored the formation of surgical centres in which many

men have attained success and celebrity at an age at which in France many others still await an opportunity to do something. Ollier would incite his countrymen to develop as much as possible their own talent, and to encourage those aspiring and talented young men who are the hope of the future in France.

This argument has a wider application than was in the speaker's mind when he made it. The hope of any country is in its young men. America is not deficient in such as are deserving of encouragement, nor, we believe, are the older men with established reputations unaware of this fact or unwilling to assist them to mount in turn to the heights which they already tread. Even now, in the field of medicine and of general and special surgery, there are a number of young men in America who owe it partly to the encouragement and assistance of those older than themselves that they have attained positions from which they may hope, if industrious and conscientious, to step in due time into the first rank. To them, and to those who would be of their number, the lesson of the hour is, not to be impatient; to those already in influential positions the appeal of Ollier may serve as a reminder that everywhere "there is that scattereth and yet increaseth, and there is that withholdeth more than is meet, and it tendeth to poverty."

In concluding his address, Professor Ollier very appropriately defined and defended a proper specialism in surgery, illustrating the advantage of the cultivation of certain special lines of practice by broad-minded and broadly-educated men by citing ophthalmology and gynæcology; to which we may add general abdominal surgery, brain-surgery, and his own admirable work in the field of diseases of the bones and joints.

In conclusion, we would join our congratulations to those of his hearers upon this excellent and suggestive address, and express our best wishes for the future of the French Congress of Surgery.

FALLACIES IN THE COPPER TESTS FOR GLYCOSURIA.

PROBABLY most physicians in testing urine to determine the presence of sugar use either Trommer's or Fehling's test, both on account of their convenience of application and of their generally supposed trustworthiness. The specific-gravity test is frequently altogether omitted, although those who have had much experience in urinalysis place a very high value upon the indications derived from the urinometer.

In a recent note in the *Boston Medical and Surgical Journal*, Dr. O. W. Sherwin states that on testing a specimen of urine with Fehling's solution the copper was reduced as with sugar. As the specific gravity of the urine was only 1015, he was induced to make further inquiry, and discovered that a small quantity of chloral hydrate had been added to the urine for preservation. He also found that the urine of persons to whom chloral had been given reacted to Fehling's solution in a similar manner to diabetic urine. The fact that the urine of persons taking chloral will reduce the copper from a test-solution has long been known. Certain other medicinal substances —as turpentine, chloroform, benzoic acid, salicylic acid, camphor, copaiba, and cubebs—will produce a similar result, if the test is made in the usual manner by heating the urine. From inquiries made recently we are forced to believe that many practitioners are unfamiliar with the above-named sources of error.

Dr. Frank Donaldson, in a paper published in the *Baltimore Underwriter* for January 5, 1887, gives the history of a man, aged 37 years, who applied for life-insurance. The personal and family history of the applicant were excellent. The urine was of a dark straw color, spe-

cific gravity 1024, acid, moderate in quantity, and free from albumen. Fehling's test showed a heavy reduction of cuprous oxide. Although there was no clinical evidence of diabetes, the application was rejected. The same fate met the gentleman when he applied to other companies. He was always turned down on the same ground by the medical examiners. A prominent medical director of an insurance company in New York told him "he had enough sugar in his urine to float a ship." These unfavorable reports induced the gentleman to place himself under Dr. Donaldson's care for treatment. For months he was "subjected to all kinds of treatment,—hygienic, dietetic, and therapeutical,"—with no change in the behavior of the urine towards the copper-solution. His health continued good, and he increased in weight and girth. Professor Tyson was called in consultation, and upon examination of the urine concluded that the reducing substance was not glucose. Professor Wormley coincided in this opinion.

Dr. Brune, of Baltimore, made an elaborate study of the urine of the same person, and found that the copper tests gave reactions similar to sugar, but that the fermentation-test and the polariscope proved the absence of glucose. Most of the gentlemen who have studied this case have come to the conclusion that the urine contains an acid heretofore unknown. The nature of this substance is now under investigation both by Dr. Brune, who is pursuing his researches at Johns Hopkins University, and by Dr. John Marshall, at the laboratory of the University of Pennsylvania, under the direction of Professor Wormley. Dr. Marshall believes the substance to be an acid not recognized heretofore.

These cases serve to point out the great caution necessary in giving an opinion based upon a defective method of examination. The low specific gravity of the urine, the small quantity passed, and the absence of all clinical evidences of diabetes, should have led to an examination of the urine with the polariscope, or to the use of the fermentation-test, before hazarding a decision.

Circulars of the State Board of Health.—Dr. Lee, the Secretary of the State Board of Health of Pennsylvania, has issued a series of circulars containing valuable advice and information with regard to contagious and infectious diseases, and especially diphtheria, scarlatina, and typhoid fever. The circulars also contain suggestions of great practical value as to prophylaxis and the preparation and management of disinfectants.

LEADING ARTICLES.

NEURASTHENIA.

In condensing the phrase "nervous asthenia"—first suggested by Dr. Fordyce Barker—into the single word *neurasthenia*, the late Dr. George M. Beard enriched medical nomenclature by an elementary title accurately designating the condition to which it is applied,—*i.e.*, "want of strength in the nerve."*

Neurasthenia is generally classed among the so-called "functional" affections of the nervous system. Beard, however, in his original paper upon the subject distinctly stated his conviction that there are definite structural alterations, although perhaps undetectable, in the nervous system, underlying the functional disorders which furnish the varied manifestations of neurasthenia. That this neurasthenic condition may eventuate in various grave or even fatal disorders is now becoming more generally recognized, and the views expressed by Beard nearly twenty years ago are daily obtaining more favorable consideration.

Arndt† has proposed a new theory of the ultimate or underlying cause of neurasthenia. According to his theory, neurasthenia is in all cases due to a defective nervous organization, the nervous supply

* Beard on "Neurasthenia, or Nervous Exhaustion." *Boston Medical and Surgical Journal*, April 29, 1869.
† Die Neurasthenie, Wien, 1886.

being inadequate to perform the functions demanded by the physical organism of which it is respectively a part. In some instances the disproportion between nervous and non-nervous tissue may be so slight that no disorder results until excessive demands are made upon the nervous power, or until some grave interference with general nutrition—*i.e.*, some depressing disease, injury, or other cause of malassimilation—makes the inequality more prominent. These are the cases which usually manifest themselves decidedly for the first time in advanced life in the broken-down business and professional man, bankrupt of nerve-force, of which this country has so large a proportion, and which seemed to justify Beard's designation of neurasthenia as a distinctively American disease. So long as food is well digested, the blood properly oxygenated, the products of retrograde metamorphosis removed from the system by normally-acting emunctories, and the brain allowed intervals of recuperating rest, the individual does not become neurasthenic. But when any one or more of these conditions fail of attainment, the shortcomings of the defective nervous organization become apparent after a shorter or longer interval.

If, on the other hand, the original disproportion between the nervous system and the rest of the organism is great, the evidences of neurasthenia are early manifested,—either in infancy, in childhood, at puberty, or during adolescence.

The trivial importance attached to neurasthenia by the majority of general practitioners often results in serious harm to the afflicted individuals. The diagnoses of hysteria, hypochondria, or syphilophobia, so frequently heard in our clinical amphitheatres, are responsible for much of the flippancy with which many of these heavily-burdened patients are treated. Lightly to accuse a woman of being "hysterical" or a man of being "hipped" may often be the gravest injustice, attaching, as it does, a stigma to the patient which may lead to permanent valetudinarianism or even to self-destruction. Dr. Emmet has shown, by his brilliant clinical studies upon the consequences of neglect of certain lacerations of the cervix uteri, how many cases of so-called hysteria are dependent upon a purely physical condition of the nerves involved in the laceration. In the light of present knowledge, the nervous symptoms of laceration of the cervix uteri must be considered as expressions of the lack of nerve-power.

The manifestations of neurasthenia, diverse as they are in causation, are no less frequent than bewildering in their multiformity. Cases now and then occur characterized by general indisposition, vague nerve-, muscle-, or bone-pains, loss of appetite, sleeplessness, depression of spirits, frequent attacks of sick headache, lack of the power of sustained intellectual application, and similar symptoms not referable to any special organ or apparatus. In other cases the languid or semi-paretic condition is replaced by nervous exaltation or irascibility. In fact, both conditions may characterize the same case at different times.

These cases might with propriety be called cerebro-spinal neurasthenia. They are exceedingly troublesome to manage, and in many instances terminate in insanity or structural disease of the spinal cord. The gradual change from soundness to unsoundness of cerebral and spinal functions in these cases is well described by Blandford* and Arndt.†

The most marked forms of cerebro-spinal neurasthenia result from extreme nervous exhaustion from any cause. Intense intellectual application in persons with a neurasthenic predisposition—in other words, with a primarily defective nervous organization—frequently determines an outbreak. Many of the leading writers, artists, and public men of the day belong to this class. Among the more prominent neurasthenics of the present century were Walter Savage Landor, Carlyle, Dante Gabriel Rossetti, Richard Wagner, and Victor Hugo. In this country two of the most distinguished women writers have recently suffered to an extreme degree from cerebro-spinal neurasthenia.

Many of these cases can be immediately traced to some traumatism, an especially large number being the consequence of railroad-injuries. Mr. Erichsen and Dr. Beard have both described a number of such cases in detail. In the sad case of the American poet John G. Saxe, now a confirmed victim to melancholia, the origin of the disease was a spinal concussion received in a railway-accident. The methods of studying the brain recently developed by M. Luys will doubtless en-

* "Insanity and its Treatment," Lecture III.
† Loc. cit., pp. 171–202.

large our knowledge of the more intimate nature of the processes concerned in the evolution of morbid psychic and motor manifestations resulting from traumatism.

Neurasthenia as effect, and probably in a measure also as cause, of local alterations of nutrition, is extremely frequent. The manifold reflex symptoms of disturbances in the genito-urinary system are simply manifestations of neurasthenia. Lallemand, Acton, Beard, S. W. Gross, Moreau, Howe, Hammond, Von Krafft-Ebing, Tarnowsky, Ultzmann, and, above all, Otis, have shown the very intimate connection between genito-urinary diseases in the male and nervous exhaustion. Not merely did the profound original researches of Otis point out the connection between urethral stricture and many nervous symptoms previously misunderstood, but his practical ingenuity gave to the profession a ready means of cure. Dr. Sayre has shown the etiological relations of adherent prepuce to epileptoid conditions, and has likewise indicated the methods of relief. In the writer's experience, an elongated and phimotic prepuce has not rarely seemed to be the cause of the train of symptoms comprised under the designation spermatorrhœa. At all events, the simple dorsal division of the prepuce has seldom failed to check promptly the frequent involuntary emissions and render the nervous symptoms amenable to appropriate treatment. In one marked case of pathophobia, under treatment two years ago, the symptoms seemed to be attributable to a frequently-recurring herpes preputialis. At all events, improvement in the psychic condition progressed *pari passu* with relief of the local disorder.

The female sex is probably subject to neurasthenia from sexual disorders to a still greater degree than the male. Emmet's epoch-marking investigations into the consequences of laceration of the cervix uteri show most conclusively the powerful influence of local nerve-lesions in the production of neurasthenia. Trustworthy authorities have stated that mental alienation may result from a continuance of marked neurasthenic symptoms. During a term of service in the Maryland Woman's Hospital and in many cases in private practice the writer has had opportunities to observe the rapid disappearance of the symptoms of nervous depression after appropriate local treatment.

Again, the manifold neurotic symptoms which attend attacks of chronic oöphoritis or pelvic peritonitis and cellulitis, and which not rarely eventuate in insanity, are evidences of neurasthenia depending upon local pathological conditions. A recent clinical contribution by Moritz Meyer* calls attention to the frequency with which certain neuroses are dependent upon local neuritic affections, and points out the appropriate remedy.

Mr. H. B. Hewetson† has also reported a number of cases of general neuroses due to eye-diseases. It is, of course, not pretended that all the cases of general neurotic disorder depending upon local affections are properly called neurasthenia; but the relation is much more frequent than is generally believed.

On the other hand, a neurotic or neurasthenic constitution may be responsible for the intensification, if not also for the origin, of the local disease. This is unquestionable in certain of the disorders of the genito-urinary apparatus in both sexes. Involuntary seminal emissions and functional impotence are notoriously frequent consequences of a lack of nerve-force. In women, ovarian irritability, amenorrhœa, and dysmenorrhœa can often be referred to the same source.

It looks very improbable at first sight that new-growths, especially cancer, should be rationally attributable to the influence of nervous depression. However, so acute an observer as Sir James Paget seems to incline to the view that such a relation may possibly exist. Snow‡ states that of one hundred and forty cases of mammary cancer analyzed by him, "one hundred and three gave an account of previous mental trouble, hard work, or other debilitating agency." Of one hundred and eighty-seven cases of uterine cancer, nearly one-half (ninety-one) gave a similar history. A number of detailed histories given by this author seem to bear out the claim that mental depression (neurasthenia) is a frequent cause of cancer. Arndt§ is positive that neurasthenia is an etiological forerunner of cancer, and relates three illustrative cases. Willard Parker‖ states that "there are the strongest physio-

* Berliner Klin. Wochenschrift, October 25, 1886.

§ Die Neurasthenie, Wien, 1886, pp. 202–208.
‖ "On Cancer," New York, 1885, pp. 40–43 and 58.

logical reasons for believing that great mental depression, particularly grief, induces a predisposition to such a disease as cancer, or becomes an exciting cause under circumstances where the disease had already been acquired." In over one-fourth of Parker's cases of cancer of the breast (one hundred and six out of three hundred and ninety-seven), nervous depression or conditions directly leading to it are set down as forerunners of the disease.

Cooke* points out the fact that in women cancer occurs on an average ten years earlier than in men, coinciding in the former sex with the menopause, and in the latter with the period of greatest exhaustion of the nervous system. He remarks that "the women of fifty are very generally more worn and wasted than the men of seventy." It is between the fiftieth and sixtieth years that neurasthenia from professional overwork is most frequent. The merchant, official, or professional man is reminded that he cannot do the same amount of work at fifty that he could at thirty: in the words of a distinguished Philadelphia teacher of the last generation, "he cannot get a three-minute pace out of a four-minute horse."

Jonathan Hutchinson† says upon the same point, "We shall probably be not far from the truth if we admit senility of tissues, local or general, to be the one predisposing cause of cancer with which we are acquainted. . . . A little step further may next be taken, in the belief that everything which hastens senility, either local or general, will increase the predisposing influence, and *in this category may be placed anxiety, distress, overwork, and excesses of all kinds. It is highly probable that under such conditions a state involving increased proneness to cancer may be induced,* and, further, *that if offsprings are produced after that state has been developed, they will inherit that tendency.*"

Parker, in commenting upon the unfriendly attitude of modern microscopical pathologists towards the theory that derangements of the nervous system may determine the origin of cancer, makes the wise observation that too close attention to the revelations of the microscope may obscure our view into the conditions underlying the visible changes. The question certainly deserves more unprejudiced study than it has heretofore received.

Disorders of the digestive system are intimately related to neurasthenic conditions. Even in persons with no demonstrable inherited nerve-weakness, any great depression of the assimilative organs results in a passing neurasthenia. Gastric or intestinal catarrhs, or disorders of the liver, or an overloaded condition of the large intestine,‡ if long continued, are nearly always accompanied by neurasthenia. Where there is an inherited neurasthenic constitution, the digestive troubles are doubtless sometimes the consequence of a foregoing nervous depression. Every practitioner sees such cases almost daily; but the relations between cause and effect often remain unrecognized. The sub-diaphragmatic self-consciousness of Carlyle was doubtless of this nature. The loss of digestive power, insomnia, mental irascibility, and unmanly treatment of his wife and friends, which characterized his later life, all point to an inherited neurasthenic predisposition. Some of these characteristics were still more pronounced in Walter Savage Landor.§

The frequency of the diagnosis of "nervous dyspepsia" is an indication that a tendency to attribute to the nervous system a share in the production of painful digestion is gaining ground. However, as Dr. Clifford Allbutt clearly pointed out in the Gulstonian Lectures for 1884,‖ what is so commonly termed nervous dyspepsia is not really dyspepsia or gastric disorder at all, but a manifestation of neurasthenia, curable only by appropriate treatment directed to the nervous system. Drs. S. Weir Mitchell¶ and Richard M. Hodges** have also pointedly called attention to the customary lack of accuracy in the diagnosis of these cases, and have given many judicious hints for their management.

GEORGE H. ROHÉ.

THE NEUROLOGICAL REVIEW.—On account of the impaired health of the editor, Professor J. S. Jewell, the *Review* will suspend publication for the present. The cordial sympathy of the profession is with Dr. Jewell, and it is hoped that he may soon be restored to health and vigor.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

THE report of the joint committee appointed by the Royal College of Physicians and the Royal College of Surgeons to consider the question of the desirability and practicability of obtaining power to grant degrees in medicine and surgery to persons who have passed the conjoint examinations of the two colleges has been presented and discussed by the governing bodies. The next step will probably be the presentation to the Crown of a petition for a charter. There are precedents in the history of several mediæval universities for the creation of a university with a single faculty: the University of Salerno, which only became extinct about a century ago, was for many generations the chief medical school in Europe, and it consisted of but one faculty; the University of Bologna at first had but one faculty, that of law; and even the University of Paris consisted originally of but one faculty, which was practically a theological faculty. The application for a charter will probably be opposed, overtly or covertly, by the University of London; the Association for Promoting a Teaching University for London will undoubtedly oppose, unless its guiding principle—the admission of representatives of the teachers in the medical schools to the governing body of the new university—is recognized. Whether these bodies have any legal right to oppose may be open to question; but there is no doubt that, before a charter is granted, the objections of existing bodies whose privileges might be injured by its grant are always listened to. The general opinion seems to be that the scheme of the two Royal Colleges may be modified, but that it will eventually succeed, and that a new university, to be called perhaps the University of Westminster, will come into existence within the next few years.

The police regulations directed against rabid dogs have been suspended in London, where they are supposed to have served their purpose; but various provincial towns have found it necessary to put similar rules in force. The British Hydrophobia Commission has not yet reported, but Professor Victor Horsley, the Secretary of the Commission, who has performed all the experiments, when speaking the other night to a paper read by Dr. Hime, of Bradford, at the Pathological Society, promised that he would shortly bring the result of his researches before that society. Dr. Hime's paper was founded on original researches made in Paris, and was chiefly directed to proving that the symptoms produced in rabbits after inoculation with the Pasteurian virus were constant and characteristic, and to rebutting the assertions made by Drs. Spitzka and Dolan with regard to the similarity of the symptoms to those following the intra-cranial injection of putrid or sterilized bouillon. The injection of virus is made into the arachnoid space, and the brain is not injured: one of the specimens shown by Dr. Hime on December 7 was a fresh preparation of the head of a rabbit inoculated in Pasteur's laboratory with rabid virus on December 4; when the skull-cap was removed, the brain was seen to be quite uninjured.

At the last meeting of the Royal Medical and Chirurgical Society, Mr. Savory read a paper founded on the examination of a series of specimens of ligature of the femoral artery for popliteal aneurism. His general conclusion from the study of a large number of cases and specimens was that, in the majority of cases of popliteal aneurism, it was more advisable to tie the popliteal artery than the femoral, and that the danger of rupture of the artery had been exaggerated. This is, of course, opposed to current teaching, as the fact that in none of the specimens examined was the artery found impervious throughout is opposed to current statements. The discussion went off on a side-track, for Mr. Bowlby was the only speaker who dealt with the question whether it is best to ligature low down; from the examination of many specimens he had ascertained that, as a rule, the condition of the artery immediately above the aneurism was rather better than its condition in Scarpa's triangle. The other speakers were chiefly occupied by the method of ligature, all expressing their preference for double ligature with division of the artery. Both these questions—the question of ligature near the sac and of double ligature—are examples of the extensive revisions of old *dicta* which the modern systems of antiseptic dressing have necessitated.

At the same meeting a paper by Mr. Treves was read on *hernia lateralis*, a condition to which he proposed to apply the term "Richter's hernia," a suggestion vigorously combated by Mr. Hulke. Questions of nomenclature are, no doubt, of but little importance, but since in the hernia in question a part only of the circumference of the gut is engaged and strangulated, the term hernia lateralis appears to be most appropriate, and better than the third suggested alternative, "partial enterocele." Mr. Treves described the symptoms as milder than in ordinary forms of strangulation, but Mr. Hulke had found them unusually acute: however this may be, it seems clear that, in some cases at any rate, the symptoms are not characteristic, inasmuch as Mr. Treves was able to quote examples where constipation was not complete, some even where diarrhœa was present, and had found that tympanitic distention was uncommon, and that vomiting was slighter, was rarely fæcal, and set in later than in cases of complete strangulation. Nevertheless, the mortality was high,—62.2

per cent.,—owing probably to the cases not being recognized.

The very good results obtained by the use of corrosive sublimate solutions in midwifery practice appear to be generally acknowledged. Dr. Boxall, who was resident medical officer to the Lying-In Hospital in York Road, Lambeth, during a period of transition, stated at the Obstetrical Society that the mortality decreased when permanganate solutions were replaced by carbolic acid, and that it fell still further when carbolic acid was replaced by sublimate solutions (one in two thousand); in the series the diminution amounted to thirty per cent. Dr. W. R. Dakin has collected cases which prove that even this valuable method of treatment must be used with discrimination; he reported ten cases of mercurial poisoning out of one hundred and sixty-five deliveries; one case ended in death. Dr. Matthews Duncan seems to have been so impressed by the liability to produce mercurialism by these injections that his practice is only to use the sublimate for occasional applications, and to use carbolic acid for the habitual antiseptic washings. Dr. Champneys, who was one of the physicians to the York Road Lying-In Hospital when the sublimate washings were introduced, and is strongly in favor of the routine use of such post-partum irrigations in hospitals, stated that in private practice he used them only for cases of operation; in such cases he washed out the vagina, and the uterus also if it had been entered by the hand, with corrosive sublimate (one in one thousand or two thousand). He left one of Ehrendorf's iodoform bougies in the uterus, and did not repeat the sublimate injections.

The Liverpool Medical Institution, on account "of the large and increasing number of cases of abdominal section in the Hospital for Women" in that city, appointed a committee to investigate "the grave questions of practice and ethics involved in the performance of these operations." The committee took ten months to accomplish their work, the delay being due partly to the illness of Dr. Imlach, who had performed most of the operations, and partly to a civil action brought against Dr. Imlach by one of his patients. The committee reported with regard to the operation of removal of the uterine appendages, that many of the patients operated on received distinct and probably permanent benefit; that to nearly an equal number the relief did not seem to have been of a decided or lasting character; and that some patients had been rendered worse. The committee insisted that the operation could not be judged on precisely the same grounds as other operations, for it considered that the removal of the organs characteristic of sex is and always will be viewed by the public and the profession with misgiving; it recommended that a consultation should always be held before performing the operation, and that the utmost pains should be taken to inform the patient, or in exceptional cases her relatives, of the nature and consequences of the operation. The impression generally left by the perusal of the report and Dr. Imlach's reply seems to have been that he has been wanting in judgment and in discrimination in the selection of cases, and that, on the whole, his colleagues of the Liverpool Medical Association have treated him with fairness.

Sir Andrew Clark has recently retired from the active staff of the London Hospital, where he has been senior physician for several years and a most active clinical teacher for many more. A committee has been formed to present him with a testimonial, and subscriptions are invited; it is intended to present him with his portrait, and at the same time to provide a replica to be placed in the library of the new college buildings. The response is certain to be liberal and hearty.

A committee has also been formed to present a testimonial to Dr. Edward Waters, of Chester, "in recognition of his earnest devotion through many years of self-sacrifice to the cause of internal medical reform." The Medical Act of 1886 is neither flawless nor final, still it is a step forward; it renders the threefold qualifications compulsory, and has established the right of the medical profession, as distinct from medical colleges, to be represented on the General Medical Council. In all that concerned this question Dr. Waters was the moving spirit in the counsels of the British Medical Association, and the general recognition of his public services in this matter combines with the high esteem in which he is held by those who have the advantage of knowing him personally to make the proposed testimonial generally popular.

Yet another testimonial has been proposed: at a meeting held in Dublin last week an influential committee was formed to raise a fund as a testimonial to Dr. Archibald Jacobs, of Dublin, who was an unsuccessful candidate at the recent election for direct representatives. Dr. Jacobs is the editor in Ireland of the *Medical Press and Circular*, and has worked hard in the interest of the general practitioner in Ireland, whose lot, always hard, is sometimes rendered almost intolerable by the exactions and parsimony of local boards.

Guy's Hospital is in great financial embarrassment; its revenues are chiefly derived from land, and the present agricultural depression has compelled the Governors to lower rents or to make at least temporary reductions; in all probability reductions now made, even though ostensibly temporary, will be practically permanent. A meeting was held this week in the Mansion House, under the presidency of the Lord Mayor, in order to attract public attention to the unfortunate position of the hospital. The Duke of Cam-

bridge stated that the annual income had fallen from forty-one thousand pounds to twenty-five thousand pounds, and that a third of the beds in the hospital were not in use. Cardinal Manning made a telling speech, strongly objecting to the scheme for placing the hospitals under governmental control, partly because he believed that the system worked badly in Paris,—it may be remembered that the religieuses have recently been expelled,—and partly because "he had *no* belief in mechanics, but a profound belief in the dynamic power of charity that had governed and civilized the world." The hospital asks for one hundred thousand pounds, and has already been promised seventeen thousand pounds. It is known that the income has been falling off for some years, and several small expedients for increasing the receipts have been tried; one of these is to "reserve" certain beds in the general wards for patients who could afford to pay a guinea a week; another is to charge out-patients threepence to defray part of the cost of their medicine: both expedients seem to be extremely unpopular with the profession in South London, and when Mr. Lushington, an ex-Indian official who some years ago was pitchforked into the important position of Treasurer of Guy's Hospital, mentioned this new application of the "advice-gratis-medicine-sixpence" principle at a meeting of the Metropolitan Provident Medical Association, his speech appears to have been brought to an abrupt termination by "signs of dissent," —*i.e.*, shouts of indignation. The reckless way in which persons who can well afford to pay are admitted without let or hinderance to the out-patient departments of most London and provincial hospitals is undoubtedly a crying scandal; but it is one for the committees of hospitals, rather than for the medical officers, to bring to an end.

DAWSON WILLIAMS.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 16, 1886, the President, A. JACOBI, M.D., in the chair.

FERMENTATION, PUTREFACTION, AND SUPPURATION.

Dr. HERMAN KNAPP, in introducing this subject, said that he was led to do so from the fact that there was a wide difference of opinion among physicians regarding the part played by bacteria in the production of disease. He had heard a distinguished professor of Berlin express the opinion that the great majority of diseases, from the modern standpoint of science, seemed to be of bacterial origin, while a short time before a professor in one of the medical colleges of New York had said that bacteriology might be important from a scientific point of view, "but practically," he asked, "what does it signify? Six diseases." This being a great contrast of opinion, Dr. Knapp asked whether it was not possible that the one overestimated and the other underestimated the importance of the subject. With a view to answering this question, he had referred to the statistics of mortality in New York and other cities for the week ending August 21, 1886, as published in the *Boston Medical and Surgical Journal*. In New York, it was stated, the death-rate from infectious diseases was thirty-three per cent.: then it was stated that the mortality from consumption was sixteen per cent., from diphtheria and croup five, and, Dr. Knapp said, as these were undoubtedly of bacterial origin, it raised the percentage to fifty-four. Of diarrhœal affections he thought at least ninety per cent. were of bacterial origin, and in the statistics quoted the percentage of deaths from diarrhœal diseases was placed at twenty in New York and as high as thirty-five in some other cities. This would raise the percentage of deaths from bacterial diseases to seventy-five. But no account had yet been taken of the deaths from pneumonia, peritonitis, endocarditis, malaria, gonorrhœa, typhoid fever, skin-diseases, and surgical affections. Reckoning these at fifteen per cent., it brought the percentage of deaths from diseases of bacterial origin up to ninety. This outcome of the figures had struck him with surprise, and, unless he had made a great mistake, they showed that the professor of Berlin was correct.

Bacteriology had shown its principal fruits in the department of surgery. Why did surgery take the lead that it did? Because of antisepsis; and antisepsis was but the application of the three terms fermentation, putrefaction, and suppuration. Dr. Knapp had repeated the experiments of Schultze, Schwam, Helmholtz, and others, demonstrating that fermentable substances from which impure air or germs had been excluded would not ferment. It had been further established that fermentation consisted in the decomposition of the carbo-hydrates by the action of the yeast-plant.

The process of putrefaction was akin to that of fermentation, only the bacteria were different, and the putrescible substance was different from the fermentable; it contained carbo-hydrates, sulphur, and nitrogen. Were the processes of putrefaction and suppuration the same? Surgeons generally used the terms so promiscuously as to lead one to suppose that they were either identical in meaning or that suppuration was a sequence of putrefaction; yet there seemed to be an important difference between them. The strong resemblance to pus observable in the changes which took place in the frog's eye a few hours

after extirpation was referred to. The surgeon asserted that if germs were kept away from a wound suppuration would not take place.

The author then stated three interrogatory propositions:

1. Does mere traumatism produce suppuration?

2. Do foreign bodies produce suppuration?

3. Do chemical agents of any nature produce suppuration?

As bearing on the first question, he said that while in Berlin he performed on rabbits all the operations which the ophthalmologist was called upon to perform on man,—on one eye with clean instruments, on the other with contaminated instruments: the wounds produced with clean instruments always healed without suppuration, those produced by contaminated instruments always suppurated. He had performed operations upon the human subject in the rudest manner, but with perfectly clean instruments, and suppuration never followed. If a simple fracture ever suppurated, it was only when there was a focus of suppuration at some other point. He therefore concluded that mere traumatism was in no way capable of producing suppuration.

Were foreign bodies of themselves capable of producing suppuration? As bearing upon this question, Dr. Knapp exhibited rabbits in one eye of which he had inserted the end of a rusty hair-pin and allowed it to remain, and into the other the end of a rusty hair-pin brought to a glow: the first eye had in every case suppurated, in the second no suppuration had taken place.

As to the third question, many of the highest authorities had asserted that chemical agents would produce suppuration. But if this apparent exception was not shown to be invalid, then the germ-theory of suppuration could not be supported. The experiments of Straus and others, and those which Dr. Knapp himself had performed, showed that chemical agents would not produce suppuration when germs were rigorously excluded. Experiments with these agents, however, were not easy; they were especially difficult with croton oil, which was extremely irritating and unmanageable. Yet even of this substance Dr. Knapp had succeeded in injecting a drop into one eye of rabbits, avoiding the entrance of germs and the formation of pus, while in the other eye, treated without precautions against the entrance of germs, suppuration developed. The best method for carrying out this experiment was that of Straus, consisting in first cauterizing the skin of the animal where the injection was to be made, and sealing the puncture by the cautery immediately on withdrawing the needle. A special hypodermic needle was recommended. While signs of irritation were present in the eye in which croton oil was injected with precaution against the entrance of germs, there was no pus and no germs; the contrary was the case when the oil was injected without such precautions. He therefore thought the proposition that no chemical agent, however irritant, would produce suppuration was pretty well established.

In conclusion, he asked, What is suppuration? He thought that, as in the case of fermentation, the cause—the microbe—entered into the definition, it should also enter into the definition of suppuration. It was said that fermentation consisted in the splitting up of the hydro-carbonates by the aid of yeast-cells; that putrefaction was the splitting up of nitrogenous substances by the agency of microbes; and it had been shown that suppuration was likewise the splitting up of nitrogenous substances by the agency of bacteria. The substances acted upon and the agencies were the same in the process of putrefaction and that of suppuration, but we speak of the process as putrefactive when the substance is a dead material, and as suppurative when it concerns living material. So we might say that putrefaction is the splitting up of dead nitrogenous substance through the agency of bacteria, whilst suppuration is the splitting up of living nitrogenous substance through the agency of the same or similar bacteria. In this way the parallelism of the three processes—fermentation, putrefaction, and suppuration—was established.

Dr. Knapp showed different kinds of micrococci.

Dr. CHARLES HEITZMAN had examined the eye of one of the rabbits in which Dr. Knapp had injected croton oil with antiseptic precautions, and, while inflammatory changes were present, yet there was not a single microbe, and he left Dr. Knapp almost a convert to his views. That suppuration and inflammation were not identical terms had been recognized by surgeons for many years. But there were conditions which it was difficult to explain on the supposition of the presence of bacteria, as, for instance, an osteomyelitis with suppuration.

The annual meeting was held January 6, 1887, the President, A. JACOBI, M.D., in the chair.

Dr. JACOBI was re-elected President, and Dr. W. H. DRAPER was elected Vice-President.

THE ANTISEPTIC TREATMENT OF SUMMER DIARRHŒA.

Dr. L. E. HOLT read the scientific paper of the evening, and said that he would refer to the etiology and pathology of summer diarrhœa only as these might have a direct bearing upon the treatment. He would state at the outset that he did not ignore other methods of treatment than by drugs. The question concerned the best treatment for that vast number of cases which crowded our institutions summer after summer, for whom no change of fresh air was possible and only

limited and imperfect dietetic regulations were practicable.

One conclusion was forcing itself upon his mind,—namely, that, with the exception of the comparatively few cases of cholera infantum, nearly all cases of diarrhœa in children were dyspeptic in origin. Excessive heat during the summer and filthy surroundings causing fermentation and putrefactive changes in the food were factors which went to bring on dyspepsia; heat also impaired the power of digestion, by depressing nervous energy. It caused thirst by excessive perspiration, and led the child to take more food than the stomach could digest; heat also increased decomposition in streets and sewers, and in the filthy tenements the children breathed atmosphere charged with the germs of decomposition. But more than all else was the change it caused to take place in the food before it entered the stomach. Regarding a microbe as being the cause of summer diarrhœa there was lack of positive information.

The indications for treatment were grouped under four heads: 1, clear out the bowels; 2, stop decomposition; 3, restore healthy action in the intestine; 4, treat the consequential lesions.

The bowels should be as empty as possible in the first step of the treatment, and for the same reason that surgeons cleansed wounds before applying a dressing. Castor oil might be given to cause a movement of the bowels, and the large intestine might be washed out by a full injection of water,—one pint of water in a child under six months, and two pints in a child under two years. Let it be given slowly with a syringe, gently manipulating the abdomen. Many mild cases of summer diarrhœa could be cured by castor oil alone, provided proper diet was adopted; but in severe cases this resulted in temporary benefit only.

The third indication was met by antiseptics and attention to diet. Antiseptics should be administered in small doses frequently, and be easy to take. A nauseous mixture should never be given. His own experience had been in favor of salicylate of sodium. If there was much vomiting, no food whatever should be administered for ten to twenty-four hours. For thirst fresh water or barley-water might be given. If the child had been weaned it was better to withhold milk for a time altogether: peptonized milk was less likely to disagree than condensed milk or even fresh cow's milk, but even peptonized milk might bring on a relapse. A diet without milk might be given of such articles as wine-whey, chicken- and mutton-broth, the expressed juice from raw beef, etc.

The fourth indication was not easily met. It consisted mainly of follicular colitis. Astringents by the mouth were of little benefit. Of importance was careful attention to diet, also antiseptics which would check intestinal decomposition, and by thus stopping the source of the irritation remove the colitis. Then the whole large intestine should be washed out once a day with pure water of a temperature of 60° or 65° F. or with a weak antiseptic or astringent solution.

Regarding the indications for opium there was much controversy. Almost all drugs which had held their place in the treatment of summer diarrhœa during the past fifty years were now recognized as antiseptics, and he thought their value was not dependent upon their astringent influence, but upon their antiseptic properties.

Dr. Holt then gave an account of the introduction of creasote, oil of naphtha, salicin, salicylic acid, etc., in the treatment of diarrhœas. Yet it was wonderful to what extent chalk, opium, bismuth, etc., were still employed. The author spoke of the treatment adopted in summer diarrhœa at the different institutions in this city. About twenty-five thousand children were treated annually for diarrhœal diseases at these institutions. Bismuth was largely used in fourteen institutions; opium was an ingredient in nearly every compound prescription given; many physicians relied nearly altogether upon bismuth and opium; castor oil was used at six; castor oil and opium at three; chalk-mixture and vegetable astringents were largely used. Astringent injections, usually nitrate of silver, were used at three institutions. Other remedies were employed, such as ipecac, rhubarb, soda, etc.

In three hundred tabulated cases treated by the author some one of the following four methods was employed: 1, chalk-mixture, paregoric, and vegetable astringents; 2, the same, preceded by castor oil; 3, emulsion of castor oil with paregoric; 4, bismuth and Dover's powder, frequently but not always preceded by castor oil.

Of these three hundred cases one hundred and sixteen were cured, one hundred and seven improved, fifty-five unimproved, and twenty-two died. Had the children been returned and the treatment always carried out, he thought the cures would have risen to one hundred and fifty-one. Twenty-seven per cent. were improved, eighteen per cent. unimproved, and seven per cent. died. While these results were certainly not such as to be proud of, he ventured to say they were as good as those obtained by others by the same method of treatment. His own impression was that many drugs which were commonly regarded as of value would not stand the test of cold facts. The cases related received as good hygienic treatment as the surroundings would permit.

These unfavorable statistics had led Dr. Holt to try other methods of treatment. Of eighty-one cases treated by salicylate of sodium, allowing as before for failure to

carry out the treatment, the percentage of cases cured was eighty-four; improved, seven; unimproved, seven; deaths, about one. This was not an overestimate of the valuable results of treatment. Some of the most striking results occurred in cases of long standing. Out of six unimproved cases, three of the patients were brought to the dispensary only once; in another the mother probably failed to carry out the treatment. The single fatal case occurred in a very wasted child with the fourth attack that summer. The diarrhœa stopped after giving salicylate of sodium, but the vomiting continued, and it died two weeks later.

Forty-four cases were treated by naphthalin alone. Sixty-seven per cent. were cured, fifteen per cent. improved, and two per cent. died (one patient). In fifty-six per cent. of the cases the disease lasted four days or less; in thirty-six per cent., over a week.

Twenty-seven cases were treated by resorcin, but the results had not been as favorable as with salicylate of sodium or naphthalin.

Twenty-eight cases were treated by bichloride of mercury, fifty per cent. being cured, twenty-one per cent. improved, twenty-five per cent. unimproved, and three per cent. died. The cases treated by chloride of mercury were the only ones which were selected. The treatment was rarely preceded by a purgative, otherwise the results might have been better.

Salicylate of sodium was given in from one- to three-grain doses every two hours, according to the age, from three months to three years. In these doses the solution was tasteless, and could be given in food or drink. He had never seen it produce vomiting. Naphthalin, though possessing a disagreeable odor, was not disagreeable to the taste, and could be given for the ages mentioned in doses of one to five grains, and it might be taken with sugar of milk.

DISCUSSION.

Dr. WILCOX had employed naphthalin in thirty-two cases of diarrhœa, chiefly in adults, and he had come to feel as much confidence in its efficacy, under certain circumstances, as in mercury in the treatment of syphilis or quinine in the treatment of malarial affections. The most frequent cause of failure with naphthalin in the treatment of diarrhœa in adults was failure to administer it in sufficiently large doses. He gave sixty grains a day, and had gone as high as one hundred and twenty grains. He gave it in capsules with the oil of bergamot. Typical cases were related in which its use had resulted in cure of chronic diarrhœa of years' duration. He had also given it in two cases of typhoid fever, and thought that it acted as an antipyretic by disinfecting the intestinal tract.

Dr. ANDREW H. SMITH said it had often occurred to him that the best way of reaching cases of summer diarrhœa was to treat them antiseptically. He thought the success attending the use of many domestic remedies was due to their antiseptic qualities,—such remedies as the mints and essential oils. As far as his experience extended, it corresponded with that of the author.

Dr. JOHN C. PETERS said that some years ago he had spoken of summer diarrhœa as "a filth diarrhœa," and he thought the treatment of it on the basis of antisepsis was correct. The common mints were among the best antiseptics. The use of pure water would result in a cure in some cases, and it should be used in all.

Dr. R. VAN SANTVOORD had had considerable experience in the treatment of summer diarrhœas in inmates of the Randall's Island Hospital, and he thought the general conclusions of the author should be strongly emphasized,—viz., that a diarrhœa was primarily a result of indigestion, and that when a diarrhœa continued, and there existed inflammatory changes within the intestine, probably caused by putrefaction and fermentation, the indications were to render digestion what it should be by preventing such fermentative and putrefactive changes. With reference to the use of opium, he had been accustomed to employ it only when the diarrhœal passages were watery and frequent, and he employed it hypodermically, guarded by atropine. He regarded the effects of bismuth as antiseptic, and not mechanical; when he employed it he gave directions for taking it after each meal. He had recently employed free injections of some astringent solution to wash out the colon, and to remove the mucus which covered the membrane he combined with the injection some alkali; he had a general impression in favor of the method. Nothnagel's observations suggested the value of adding a little salt.

The PRESIDENT heartily agreed with what Dr. Holt had said regarding antiseptic treatment. Thirteen years ago he expressed in a paper the view that bismuth was an antifermentative. He thought it was impossible to relieve a severe attack of summer diarrhœa without stopping the ingestion of milk for a number of days. There were plenty of substitutes, and the one which he had used most was the raw white of egg mixed with some farinaceous substance, usually with barley-water. While raw beef was often beneficial, its use was attended with the danger of developing tape-worm.

Dr. G. L. PEABODY had during the last year come to look upon naphthalin as a very valuable addition to our remedies in the treatment of a variety of intestinal complaints. He was confident he had seen several cases of typhoid fever which had entered the hospital in the early stage of the disease apparently aborted by naphthalin. He gave sixty or eighty grains during the twenty-four

hours, in repeated doses. In a man who had diarrhœa for twenty-one years, with never fewer than seven movements a day, naphthalin was employed, and within ten days he was entirely cured. Other severe cases had been treated with this drug with marked results.

Dr. W. W. CARPENTER, as bearing on the antiseptic treatment of diarrhœas, said he had seen greater benefit from the regular use of old cider—a glassful three times a day—than from any other remedy, in patients who had contracted the diarrhœa when in the war of the rebellion. He had also seen chronic cases of diarrhœa—those dysenteric in character, and also some of the tubercular variety—greatly benefited or cured by salicin.

Dr. HOLT closed the discussion, and said that Dr. Caldwell had used the salicylate of sodium in the diarrhœa of phthisis, which resembled the diarrhœa of children, obtaining uniformly good results.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, DECEMBER 27, 1886.

The President, LAWRENCE JOHNSON, M.D., in the chair.

THE TREATMENT OF HERNIA BY SUBCUTANEOUS INJECTION.

DR. W. DE GARMO, the author of the paper, said that the year 1877 had marked an era in the treatment of hernia, owing to the publication of Heaton's method, which had been practised, but kept a secret, by Heaton since 1843. The object of methods of treatment prior to that time had been the destruction of the hernial sac, but Heaton made no attempt to do this. The object in injecting his fluid was not to produce inflammation; it was to fortify the fibrous tissue surrounding the canal so that protrusion would not recur.

Dr. De Garmo had operated by Heaton's method during the past seven years in over one hundred cases, furnishing abundant evidence of its value and its freedom from danger. The failures with it in the hands of some he attributed to the erroneous method of operating and the want of proper after-treatment. For instance: in invaginating the scrotum with the finger introduced into the canal, unless proper precaution was taken, the fluid would be injected into the base of the scrotum; the fluid was not brought in contact with the proper tissues; it was sometimes allowed to return in the track of the needle. Some surgeons had allowed their patients to go without a support from the moment of rising from the bed at the end of a week or ten days, and some had even asked them to cough or strain, in order to test the effects of the operation. It was needless to say that the hernia would return in all such cases. The after-management is as important as the manner of operating. The patient, after being confined to bed for seven or ten days, or even fourteen days in severe cases, should, on rising, wear a truss. But too firm pressure should not be made, as it tended to weaken the tissues which it was desired to strengthen. In March last he called attention to a modification of Heaton's method for patients who were unable to remain abed after the injection. It consisted in repeated injections of a small amount of the fluid, the patient wearing a truss and continuing at his business. The operation, in his experience, had resulted in cure in forty-five per cent., and the percentage of cures would reach fifty or seventy-five per cent. in selected cases. Benefit always resulted, even in the worst cases, the patient being enabled to retain the hernia by the aid of a truss, which he had before been unable to do. Children who had not been cured by an instrument could always be cured by Heaton's method. Dr. De Garmo was not disposed to change from Heaton's fluid, which consisted of fourteen grains of the solid extract of white-oak bark to the ounce of the fluid extract, rubbed up together.

Dr. R. F. WEIR had done Heaton's operation in about seventy or eighty cases, and his cures had been nearer one-third than one-half.

A CLINICAL STUDY OF NEURALGIAS IN NEW YORK.

Dr. DANA made two subdivisions of his paper: 1. Had the neuralgias of New York the same physiognomy as those of Europe? 2. The reflex origin of neuralgias and neuralgic pains.

True idiopathic neuralgia was a rare disease, not constituting over two or three per cent. of all cases of nervous disorders. Sympathetic neuralgia was frequent. The neuralgias in New York which formed the basis of his studies occurred in 250 of his own patients and in 252 seen by other physicians in private or dispensary practice: trigeminal neuralgia constituting 43 per cent.; sciatic, 23 per cent.; intercostal, 13; cervico-occipital, 4.5; lumbo-abdominal, 2.5; articular, 2 per cent. One-third of all the cases occurred before the twenty-fifth year, and two-thirds before the thirty-fifth year; the ratio of males to females was 3 to 5; the greatest number of cases occurred in the winter, the fewest in spring. The greater proportion of neuralgias in this country occurring in early life he regarded as showing a less number of the degenerative and violent types.

As to neuralgia of special nerves, the branches of the fifth pair were affected the most frequently: out of a hundred cases, the supra-orbital was affected in thirty-three per

cent; there was migraine in thirty-one per cent., mixed forms in seventeen per cent., infra-maxillary in five per cent., tic-douloureux in five per cent., and infra-orbital in three per cent. Of these cases, about two out of three were females. There was an increase of trigeminal neuralgias between the thirty-fifth and forty-fifth years. In all neuralgias, the left side was affected in about three out of five cases. Most cases of migraine and supra-orbital neuralgia were worse in the morning, especially those curable by quinine and arsenic. As to causes, child-bearing, anæmia, and exposure were common. The nervous temperament was often present. The cases of migraine in which the face was flushed red were rare. In nearly all cases it was a family disease, alternating at times with other neuroses. Almost all responded well to treatment. He had not been able to convince himself of any connection between the cases and nasal or pharyngeal irritation. One case showed a relation to trouble with the eye. He did not regard migraine as due to an affection of the vaso-motor system: it belonged to trigeminal neuralgias.

Much had been said about the reflex origin of intercostal neuralgias, but in his experience only a small proportion of the cases were of reflex origin. Probably one-half the pains in the left side were myalgic. Neuralgic, myalgic, and neuro-myalgic varieties should be recognized in the treatment.

Reflex influence in the production of neuralgias had probably become exaggerated in the minds of physicians, but they were of sufficient importance to deserve further study. According to numerous reports of cases, almost any surgical operation about the head would cure ninety per cent. of migrainous patients. He thought we might speak of a pseudo angina pectoris of gastric origin. The stomach and intestines were the most frequent causes of reflex pains; second, he thought, was the uterus.

In his conclusions, he said that reflex pains were pains reflected from a lower to a higher level; they occurred, as a rule, when the irritation was severe over the part where the irritation existed. Reflex pains originating in one cerebro-spinal nerve were referred to other cerebro-spinal nerves, and those originating in visceral nerves were reflected to the cerebro-spinal nerves,—rarely the reverse. Reflex pains were unilateral when the cause was unilateral, and were felt on the same side. There were occasional exceptions to this rule. Remote reflex pains were only produced when the irritation was slight. Diffuse irradiation of the pains meant an impaired state of the nervous system. Reflex pains of visceral origin were carried by the cerebro-spinal nerves to the cord, and thence to the brain, and not by way of the pneumogastric. He did not believe the pneumogastric to be a sensitive nerve of the viscera.

The paper was discussed by Dr. W. O. Moore and Dr. Putnam Jacobi, and the discussion was closed by the author.

PHILADELPHIA NEUROLOGICAL SOCIETY.

A STATED meeting was held December 27, 1886, the President, Dr. S. Weir Mitchell, in the chair.

Dr. Guy Hinsdale read a paper entitled

FACIAL SPASM AND TIC DOULOUREUX FOR WHICH NEURECTOMY AND NEURO-TENSION WERE EMPLOYED (see page 278).

DISCUSSION.

The President, Dr. S. Weir Mitchell: I have several points to make with reference to these cases. The woman operated on by Dr. Keen I have seen within the past few days, and she presents no paresis of the face at all. As yet the case is a perfect success. She is entirely free from any twitching. Her case recalled others, and in looking over my note-books I found that within the past twelve years I had seen fifteen cases of painless tic, in none of which was the slightest relief afforded by any method of treatment. It so happened that shortly after Dr. Sinkler's case was treated so successfully, Mrs. G., aged 49, the widow of a physician, a very intelligent woman, consulted me. She stated that her tic had begun about three years ago. It first appeared under the eye, where it nearly always begins, although I may say that as yet the history of these cases is not complete. Then the twitching appeared in the cheek, which, as a rule, has been the point next attacked in my cases. The spasm afterwards extended to the mouth. In those cases in which it became general it extended beyond that, and in the last case that I have seen the levator muscles of the ear were involved, so that the ear was drawn upward every time that the face twitched. But extension to the neck or more distant parts is seen at times in rare cases.

In Mrs. G. the spasm was very violent, and she described it by saying that "the whole side of the face migrated under the left ear and stayed there awhile." The length and endurance of the spasm were remarkable. She had from ten to fourteen attacks every minute. They were pretty regular. At certain times she was comparatively free, but scarcely five minutes passed without twitching.

I observed in this case, as in some others, a certain amount of appearance of paresis on the affected side of the face,—that is to say, the muscles on the sound side of the face appeared to predominate. I have so far been unable to observe any difference in the electrical reactions of the affected muscles. Perhaps more careful observation will show some change. It has been suggested to me that this paresis was the result of fatigue; but, as we

know, in most spasms the muscles become larger and stronger and do not present evidences of fatigue.

In this case I began to think whether there was not something which had not been done which might give relief. The idea of weakening the facial nerve or its branches by freezing suggested itself. If I had reflected a little I should have recognized the fact that it is impossible to affect the deeper nerves in this way. Freezing by vapor-jets applied to the surface acts very little beneath the skin. I have tried this by putting the finger in the mouth and trying to freeze through the cheek by means of the rhigolene spray. I have never succeeded in producing more than a slight chilling. In this case I have on sixteen occasions frozen with the rhigolene-jet a large portion of the skin of the cheek, sometimes covering the whole of the side of the face, taking care to protect the eyes and to prevent the inhalation of the vapor.

The result has been an interesting and a curious one. The very first freezing, like all the subsequent ones, brought on instantaneous spasm. The moment the jet struck the face there was violent twitching. When freezing was effected the spasms ceased and did not return for many hours. This result surprised me very much, and it appeared that while I was attempting to accomplish the result in one way I had done it in another.

Under these daily freezings this case has gained so far as to pass days without more than such rare twitches beneath the eye as excite no attention. Enough has been won to satisfy her if the gain should last, as to which I will report.

I observed that a vigorous freeze over the points of nerve-exit was better than a general freeze. I am about to try if localized freezing by ice and salt or other means which act more deeply may not answer. The influence *seems* to be exerted through the sensory nerves, from which possibly arise also the impressions which create these spasms. With my remembrance of former cases, I cannot say that I feel hopeful as to the remote future of the present one.

I have tried the same plan of treatment in a second case of nine years' standing. She came to me some years ago, but, as I knew of nothing that would afford relief, I refused to treat her. I sent for her ten days ago, and began the use of the rhigolene spray. She too has slight paresis. The face is apparently pulled to the right, the spasm being on the left side, which is the side commonly affected. The results obtained with the individual freezings are practically the same as in the first case. The touch of the spray brings on the spasm. When the part is frozen the spasms remain absent for a considerable length of time, although not so long as in the first case. The period varies from half an hour to two hours. Under this plan of treatment the attacks have diminished in frequency and in intensity.

This is as far as I have gone, but I thought it well to bring this matter before you, for some of you may have one of these rare cases under observation and may desire to try the same experiment. As we know of no method of treating these cases except by operation, I consider it perfectly proper to try the effect of rhigolene. After the spray has been used for some days, care must be exercised that a slough is not produced. I have never had a slough, although I have made the skin very sore. This has led me to think that possibly the good result was due to counter-irritation, and I shall not be satisfied until I have tried extensive counter-irritation over the origin of the facial nerve in some suitable case.

Dr. J. Madison Taylor: I have had under my care a case in which a severe spasm of the right side of the face had been present for twenty years. The woman was nervous, and came of a family many members of which were in a general way nervous, yet quite strong and robust. The spasm, although very annoying, was not sufficiently marked to call for special treatment. About fourteen months ago the youngest daughter of this woman passed through a severe attack of typhoid fever. The mother, from nursing the child, became very much exhausted. Then the spasm grew worse, and was at times sufficient to shake the head. When the child became convalescent the mother was taken with the disease and had a severe attack, with high fever and delirium for six days. Upon her recovery from the typhoid fever the spasm had entirely disappeared, and to the present time, a period of ten or twelve months, there has been no return. It is interesting to note the curative effect of a severe illness on this intractable disorder. Hers was a veritable purgation with fire.

(To be continued.)

REVIEWS AND BOOK NOTICES.

How We Treat Wounds To-Day. A Treatise on the Subject of Antiseptic Surgery which can be Understood by Beginners. By Robert T. Morris, M.D. New York and London, G. P. Putnam's Sons, 1886.

The subject of the antiseptic system of dressing wounds (without the spray) is presented in this work in a terse, familiar, and dogmatic style, which may convince some surgeons who have not yet had it presented as directly to their attention as it is here, but it is probable that many will be repelled by the style of the writer. One could be excused, however, for feeling and expressing himself strongly who daily sees operations performed, with

safety to the patient, which under the former methods were attended with prolonged suppuration, and in spite of the utmost care frequently terminated fatally,—operations, indeed, which under other circumstances would be properly regarded as unjustifiable. Besides the technique of antiseptic treatment, its application to various kinds of wounds—lacerated, gunshot, or poisoned—and burns is specifically discussed.

Sixth Annual Report of the State Board of Health of New York. Transmitted to the Legislature March 19, 1886. Albany, New York, 1886.

In the Secretary's report a number of interesting topics are considered. The relations of pulmonary consumption and cerebro-spinal fever to faulty drainage and high ground water; the prevalence of filth diseases, the history of the last year's smallpox epidemic upon our borders demonstrating again the protective value of vaccination, and the futility of relying upon quarantine alone to exclude contagious disease; an outbreak of typhus fever; a discussion of the fallacies of the chemical analyses of water, and the importance of a biological test, are the principal topics considered in the Secretary's able report. Reports from the Sanitary Committee, of inspection of localities and upon the sewerage of Binghamton, accompanied with maps, are given, and a report of the State Analyst of Drugs is appended, with special reports on quinine pills and on beer. The report of the Standing Committee on Registration and Vital Statistics and appended documents also contains much interesting and valuable materials, gathered from actual inspection.

An Ephemeris of Materia Medica, Pharmacy, Therapeutics, and Collateral Information. January, 1887.

The first number of Volume III. of Squibb's Ephemeris contains valuable articles upon hydrochlorate of cocaine, opium, and aconite, in addition to interesting notes on medicine and pharmacy abroad, the relations of physicians to their medical supplies, and the alcohol question before Congress. The Ephemeris will continue to be published at intervals, according to the accumulation of materials.

Coca Erythroxylon (Vin Mariani). Its Uses in the Treatment of Disease. With Notes and Comments by Prominent Physicians. Third Edition, Paris and New York.

This little work gives a satisfactory *résumé* of what is known of coca, and especially of its application to the treatment of disease in the form of Mariani's wine. Among the names of those furnishing testimonials as to the benefit derived from the coca-wine are those of many prominent artists and physicians. A copy of this monograph will be sent free by the publishers to any address. Mariani & Co., 127 Fifth Avenue, New York.

The *Archives of Gynæcology, Obstetrics, and Pædiatrics*, New York, series of 1886, just completed, has met with such warm encouragement that the publishers have decided to issue them monthly, instead of bi-monthly, as heretofore, commencing with January.

NEW REMEDIES AND CLINICAL NOTES.

An Experimental Study of Mycotic or Malignant Ulcerative Endocarditis.—Malignant ulcerative endocarditis is a form of lesion always associated with some kind of bacteria. The causative relations of these bacteria to the lesions are points upon which Dr. T. Mitchell Prudden seeks to throw some light in a recent paper.

Dr. Prudden shows that bacteria are frequent in a certain proportion of cases of acute ulcerative endocarditis in the cardiac and, when these exist, in the peripheral lesions. These bacteria are small and of spheroidal form in almost all the cases thus far described; but in a few cases the presence of bacilli has been noted. There are cases of ulcerative endocarditis with extensive destruction of tissue and large formation of thrombi, in which the lesions are entirely free from bacteria. In these cases, as a rule, the endocardium is the seat of an old inflammatory process, and the peripheral embolisms, infarctions, etc., do not contain bacteria. In many cases of acute ulcerative endocarditis associated with bacteria, the valves and endocardium are also the seat of old inflammation.

The destructive process and formation of thrombi in the heart-valve and endocardium may be as marked and extensive in the cases in which the bacteria are absent as in those in which they are present; but in the latter class of cases the embolic lesions which are apt to be developed are of an infectious nature, and the general course of the disease is apt to bear the stamp of an acute infectious disorder.

The gross appearance of the valvular lesion does not always or usually enable us to distinguish between these two forms of disease. Bacteria are sometimes present in cases of acute vegetative endocarditis, but in the lesions of chronic proliferative endocarditis they do not appear to occur at all. The bacteria which are present in the cardiac and peripheral lesions in cases of malignant ulcerative endocarditis are the causative factors in the disease. The bacteria apparently produce the cardiac lesions by lodgement on the surface of the valves and endocardium, when the latter are rendered vulnerable to their action either by

mechanical or chemical injury, or by the presence of old inflammatory alterations, or by conditions unknown to us. Bacterial embolism of blood-vessels of the heart-valves is apparently not of frequent occurrence, as was formerly believed.

The only bacteria which have been thus far absolutely identified as occurring in the lesions of malignant ulcerative endocarditis in man are Streptococcus pyogenes and Staphylococcus pyogenes aureus. This identification has been made in six cases. Dr. Prudden has demonstrated that other species of bacteria than those mentioned are capable of causing similar lesions in rabbits under similar experimental conditions.

Finally, Dr. Prudden points out that, in view of the significant relationship of the bacteria of pyæmia and suppuration to malignant ulcerative endocarditis in the cases thus far fully examined, it is evident that a demonstrably diseased condition of the heart-valves, or a previous history which would suggest the possibility of such a condition, should be an additional incentive to the practice of a vigilant antisepsis in operations, however simple, upon this class of cases.—*American Journal of the Medical Sciences.*

On Some Forms of Albuminuria not Dangerous to Life.—The gravity of albuminuria as a symptom has been differently estimated at different times, but gradually it has come, in recent years, to be known that albumen often appears in the urine, even in considerable quantity and very persistently, in persons free from important organic malady. Indeed, it may be maintained that some patients with persistent albuminuria are yet eligible for life-insurance at little, if at all, above ordinary rates.

It is, therefore, important to know the characteristic features of these non-dangerous albuminurias and in general the pathological import of this symptom in a given case.

Dr. Grainger Stewart, in the same journal, studies the following varieties: 1, paroxysmal albuminuria; 2, dietetic albuminuria; 3, albuminuria from muscular exertion; and, 4, simple persistent albuminuria; and illustrates each with reports of cases which are markedly characteristic.

The diagnostic features of paroxysmal albuminuria are the sudden and copious occurrence of albumen in the urine with numerous casts, the process lasting only a short time and recurring at intervals with or without a perceptible exciting cause. The exciting cause, according to Dr. Stewart, is irritation of the kidneys from blood-changes. The treatment should be directed, on the one hand, to the avoidance or diminution of renal irritation, and, on the other, to the regulation of the hepatic function and of the chemical processes in the body. Happily, the attacks are usually of brief duration, and he has never known them prove permanently injurious.

Dietetic albuminuria is a variety which has long been more or less distinctly recognized. Some people suffer from it whenever they indulge in certain articles of diet. In some cases one kind of food, in others many require to be proscribed: cheese, pastry, and eggs are among the more common offenders. Of this group our present knowledge does not suffice to afford a satisfactory explanation.

The cases of albuminuria following upon muscular exertion Dr. Stewart is disposed to attribute to a general change in vascular activity. The principal indications for their treatment are met by rest, judicious diet, and attention to the general health. Those remedies which act upon the muscular fibres of the vessels deserve trial.

The features of simple persistent albuminuria are the constant presence of albumen, usually in small quantity, unattended by tube-casts, diminution of urea, increased muscular tension, cardiac hypertrophy, or other consequence of renal malady, persisting for a period of months or years, and little influenced by diet or exercise.

Dr. Stewart concludes his study with a consideration of the prognosis of these groups, placing special dependence upon the quantity of the urea, the presence or absence of tube-casts, and the condition of the pulse and heart. This will indicate whether simple albuminuria or organic disease is present, and if they are favorable a hopeful prognosis may be given.

Actinomycosis Hominis.—Actinomycosis is a progressive inflammatory affection set up by a certain fungus, the actinomyces, resulting in the formation of granulations and fibrous tissue and in suppuration; attacking human beings, cattle, and swine, and communicable to cattle by inoculation. The fungus occurs as small globular masses, commonly about the size of a millet-seed, usually of a pale-yellow color, but at times white, brown, green, or speckled, with a surface closely covered with palisade-like rows of clubbed bodies which give it a mulberry-like appearance. If seated in the tissues, each portion of fungus is surrounded by inflammatory products forming a nodule which in its structure may exactly resemble a tubercular granulation. In the *American Journal of the Medical Sciences*, Dr. E. Markham Skerritt gives a *résumé* of our knowledge of the disease, and reports a case in which one lung had been previously attacked, and which presented certain features of special interest.

The etiology of the disease is still obscure. The micro-organism has never been recognized outside the body, and, apart from inoculation experiments, no direct relationship between the disease as occurring in the lower animals and as met with in man has been

established. There is strong evidence to associate the occurrence of the disease with the existence of carious teeth or dental fistulæ. The fungus may enter the body, however, by the mouth, pharynx, respiratory passages, or digestive tract. Wherever the primary seat may be, in any case of actinomycosis, generalization of the fungus by embolism may occur, with resulting recurring rigors and hectic and secondary foci of infection.

Prolonged Gestation.—Dr. J. Cheston Morris reported to the Academy of Medicine the following case, which occurred in his practice in 1857. He found the patient, contrary to her belief, three months pregnant in May; she quickened about June 20, and presented no unusual symptoms until the 20th of August, when she fell down a flight of stairs, and soon after lost a large quantity of blood, which she insisted was liquid only. The motion of the child ceased from three to four weeks, when they recommenced, feebly at first and afterwards stronger, which continued until delivery, April 18, 1858, there being nothing abnormal about the child. After careful study, he was forced to believe that the woman carried the child for fourteen months. This led to an investigation of the duration of pregnancy, which is usually held to last during ten lunar months. In order to have a help in this research, he made use of a study of gestation in the lower animals. For twenty years he kept a record of a flock of sheep on his farm. This period has been usually assumed to be one hundred and forty-seven to one hundred and fifty days. But in fact he had reported one hundred and twenty-six pregnancies with an average of one hundred and sixty-four and a half days' duration. In 1878 the flock appeared to be suffering from an epidemic of scarlatina, and the duration of gestation varied between the extremes of one hundred and forty-six and one hundred and ninety-nine days.

Whenever practicable, he had collected histories of human pregnancies which could be assigned to a certain fixed time, and out of a list of twenty-five selected with care, the limit varied between the limits of two hundred and fifty to two hundred and ninety-one days.

Addison's Disease in a New-Born Infant.—Dr. E. Belaiëff, of Voronej, details in the *Meditzenskoie Obozrenie*, No. 1, 1886, page 54, a unique case of Addison's disease in a new-born male infant. No case occurring in a child younger than three years of age has ever been recorded. The child had been deserted, and was found lying on the pavement. It appeared to be about seven days old. The integuments were slightly yellowish, with a gray tint. Later on, the yellowish discoloration disappeared, while the skin gradually assumed a dirty-gray color, which was most intense on the back and belly, especially around the navel. Notwithstanding a good appetite, the infant steadily became prostrated and emaciated, and fifty-three days after admission died in an unconscious state during a paroxysm of tonic and clonic convulsions. There was no fever from the beginning to the end. At the necropsy both supra-renal capsules were found considerably enlarged (one by three-fourths inch), their upper two-thirds being transformed into an aggregate of thin-walled, semi-translucent cysts, the size of which varied from that of a pin's head to a small cherry. The cysts contained clear serous fluid.—*British Medical Journal.*

Ingluvin.—An infusion made with the inner membrane of the gizzard of the chicken is said to be a domestic remedy in long use in some portions of this country for the relief of weak digestion, and it has been used in a similar way for many years in China. The powdered dried membrane was highly recommended for such condition by the late Professor Ellerslie Wallace, of the Jefferson Medical College. Ingluvin has been made by Mr. W. F. Warner, in order to meet the demand created for it very largely by Dr. Wallace's praise of it, especially in the vomiting of pregnancy. It is a yellowish-gray powder, and is given, like pepsin, in three- to ten-grain doses in the disordered stomach during gestation, cholera infantum, diarrhœa, and flatulence with indigestion. As it has no irritant effect, it can be given in inflammatory conditions of the mucous membrane. Bartholow recommends it for the relief of vomiting, especially during pregnancy.

For Diarrhœa in Children.—

℞ Ferri sulphatis,
Sodii salicylatis, āā gr. xx;
Glycerini, f℥ij;
Aquæ q. s. ad f℥iij.

Dissolve soda and the iron salts separately, and mix the solutions. One teaspoonful should be given every hour until the stools are blackened (in about twenty-four hours); afterwards every three hours. Occasionally a small dose of castor oil is given, in order to clear the bowels and get the secondary constipating effects of the oil.—Braithwaite: *British Medical Journal.*

MISCELLANY.

Fire-Proofing Wood.—A mode of rendering wood incombustible not generally known is described as follows: Soak 27.5 parts by weight of sulphate of zinc, 11 of potash, 22 of alum, and 11 of manganic oxide in lukewarm water in an iron boiler, and gradually add 11 parts by weight of sixty-per-cent. sulphuric acid. The wood to be prepared is placed upon an iron grating in an apparatus of suitable size, the separate pieces being placed at least an inch apart. The liquid is then poured into the apparatus and

the wood allowed to remain completely covered for three hours, and is then air-dried. The mode of application described is, we fear, a serious obstacle to the general use of this process for timber employed in building, especially as the rough timber, before being worked or framed, could only be conveniently treated in this manner. If joists, ceiling-beams, and all joinery exposed to fire could be treated after being fixed with some chemical solution of proved resistance to the action of flame, we believe many architects would be found to employ it.—*Druggists Circular.*

INTERNATIONAL MEDICAL CONGRESS, VACANCIES FILLED.—Dr. J. J. Chisolm, of Baltimore, Maryland, has been appointed President of the Section of Ophthalmology, in place of Dr. E. Williams, who was compelled to resign on account of ill health. Judson B. Andrews, M.D., Superintendent of the Hospital for the Insane at Buffalo, New York, has been appointed to the place made vacant by the death of Dr. John P. Gray, as President of the Section of Psychological Medicine and Nervous Diseases. No vacancies now remain in the list of the chief officers of the preliminary organization of the Congress or its Sections, and our information from all departments is of the most encouraging character.—*Journal of the American Medical Association.*

ON the 29th of December the course of the Training School for Nurses at the University of Pennsylvania was formally opened. The first lecture was on "Treatment of Fevers." It was delivered by Professor William Pepper.

INSTRUCTION IN MASSAGE.—Dr. Benjamin Lee, No. 1532 Pine Street, has begun a course of lessons in massage and the simpler Swedish movements. Classes are limited to six.

ANTIFEBRINE (acetanilide) has been used quite extensively by M. Dujardin-Beaumetz in the treatment of epilepsy. It is believed to be one of the most powerful "moderators" of the special centres that we possess.—*Lancet.*

MR. LAWSON TAIT has had conferred upon him by the University of the City of New York the honorary degree of M.D.

NOTES AND QUERIES.

EXTRACT OF MALT AS A THERAPEUTIC AGENT IN TABES AND TUBERCULOSIS.

HAVING had marked success in the use of Johann Hoff's Malt (Eisner's), I deem it proper to report a few cases.

Case I.—On the 25th of November, 1886, I was called to see P. R., æt. 5 months. Father has tuberculosis, mother strong and healthy, nursing the child at the breast. Hygienic surroundings bad, house damp. The child has had a cough almost since birth, which has been growing worse; he has been losing flesh; marked emaciation; vomits occasionally through the day. Bowels regular, containing at times muco-purulent matter, most likely from the lungs. Pulse weak and rapid, tongue coated, child peevish. Physical signs: large and small râles in various parts of both lungs; prolonged expiration; percussion-dulness at various points. The child was placed upon half-teaspoonful doses of Johann Hoff's Malt four times a day. I wish to call particular attention to the fact that this extract should be administered warm in cases of lung-disease.

December 9, 1886. The child is much better, the cough slight, appetite improved, vomiting ceased. The stools contain very little muco-pus. Respiratory sounds approaching the normal; the dulness is clearing. Ordered teaspoonful doses of the Extract four times a day.

January 6, 1887. The child has been well for more than a week. He is well nourished, pulse strong, stool normal. The cough has disappeared, lung-sounds normal. Child discharged cured. Diagnosis, tabes.

Case II.—H. B., æt. 6. Had nasal diphtheria on October 28, 1886; was fully recovered on November 17. About December 6 the mother noticed an impediment in the child's speech and sent for me. The patient was markedly anæmic, spoke with a nasal twang, and severe attacks of coughing followed the act of swallowing liquids. Diagnosis, diphtheritic paralysis of the pharynx. Treatment: strychninæ sulph., gr. $\frac{1}{60}$, quininæ sulph. and ferri sulph., āā gr. ss, in pill three times a day.

December 12. Child slightly improved. Stopped the pills and ordered teaspoonful doses of Johann Hoff's Malt four times a day.

January 4. The child has made a complete recovery.

Case III.—I was called to attend Mrs. M. W., æt. 42, on December 13, 1886. Her family history is good. Was perfectly well up to four months ago. Her husband died a year ago of phthisis. Physical examination revealed the early stages of tuberculosis, affecting the left lung. Debility has been so marked that she has not been able to get out of bed for the last five weeks. The cough is very troublesome, pulse weak. Ordered a wineglassful of the Johann Hoff's Malt four times a day.

December 24, 1886. The patient states that before she had emptied the first bottle she was able to walk across the room. At this date she is down-stairs; is much stronger; pulse improved; cough not so troublesome; chest-sounds markedly improved.

January 6, 1887. Patient has gained very much in strength, and is able to attend to her household duties. The future progress of this case will be reported.

J. B. POTSDAMER, M.D.
1629 NORTH EIGHTH STREET, PHILADELPHIA,
January 6, 1887.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 2, 1887, TO JANUARY 15, 1887.

LIEUTENANT-COLONEL JOSEPH C. BAILY, ASSISTANT MEDICAL PURVEYOR.—Ordered from Department of the East to New York City, to take charge of the medical purveying depot in that city, relieving Captain Henry Johnson, Medical Storekeeper, from duty as acting assistant medical purveyor. S. O. 9, A. G. O., January 12, 1887.

MAJOR HARVEY E. BROWN, SURGEON.—Granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Missouri. S. O. 9, A. G. O., January 12, 1887.

CAPTAIN J. K. CORSON, ASSISTANT-SURGEON.—Ordered to Fort Cœur d'Alene, Idaho Territory.

CAPTAIN C. E. MUNN, ASSISTANT-SURGEON.—Ordered to Fort Canby, Washington Territory.

FIRST-LIEUTENANT J. M. BANISTER, ASSISTANT-SURGEON.—Ordered to Fort Cœur d'Alene, Idaho Territory. S. O 227, Department of the Columbia, December 31, 1886.

CAPTAIN RICHARDS BARNETT, ASSISTANT-SURGEON.—Leave of absence further extended six months, on account of sickness. S. O. 9, A. G. O., January 12, 1887.

FIRST-LIEUTENANT GEORGE F. WILSON, ASSISTANT-SURGEON.—Leave of absence extended twenty days. S. O. 9, A. G. O., January 12, 1887.

FIRST-LIEUTENANT H. I. RAYMOND, ASSISTANT-SURGEON.—Ordered for duty at Presidio of San Francisco, California. S. O. 127, Department of California, December 29, 1886.

FIRST-LIEUTENANT F. J. IVES, ASSISTANT-SURGEON.—Granted one month's leave of absence, with permission to apply for twenty-three days' extension. S. O. 1, Department of the Platte, January 3, 1887.

PHILADELPHIA, FEBRUARY 5, 1887.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF APOPLEXY; AND ON THE USE OF COCAINE AS A HEART-TONIC AND STIMULANT IN TYPHOID AND OTHER LOW FORMS OF FEVER.

Delivered at the Pennsylvania Hospital, December 18, 1886,

BY PROF. J. M. DA COSTA, M.D.

GENTLEMEN,—The first case to be brought before you this morning is that of an elderly man who has had an attack of apoplexy. In the first place I must state that the early history of this case is not beyond doubt, because the patient was not in a condition to give us much information. However, we have ascertained, from his friends chiefly, that this man had been healthy during the greater part of his life; he had been accustomed to the moderate use of alcohol; venereal infection is denied. His occupation is that of porter in a wholesale tobacco house. He had been in good health and felt well—so he states since he has become more conscious—until the day of admission, which was three days ago. After working as usual through the morning, at two o'clock in the afternoon he dropped a piece of paper, and he stooped to pick it up with his left hand, but found that he could not do so. A few minutes later he lost power in his left leg as he was going home, and nearly fell in the street. He states positively that he had neither headache, nausea, nor loss of consciousness either before or during the attack. We found, after he was brought here, that his mind was clouded; but since his mental condition has cleared he declares that he retained possession of his senses, and knew everything that was going on around him, although he could not speak; he was dazed rather than unconscious. He was brought here on the evening of the mishap.

Upon admission his temperature was 98° in the axilla. His face was drawn to the right, his tongue was protruded to the left. There was no marked inequality of the pupils, and no strabismus. There was almost complete loss of power in the left arm, and decided weakness of the left leg. He was very restless. His mind was clear, his voice was indistinct; he answered questions correctly, but not distinctly. Although upon admission some of his answers led us to think that he did not know very well what he was saying, yet he always made the attempt to answer questions.

Two drops of croton oil were given at once, which purged him freely. Next morning his mind was considerably clearer; he stated himself that he had had headache the night before, but none in the morning.

On the 16th his mind was clear; his pulse, which on the evening after admission was 80, with a temperature of 98°, in the morning was 78, and the temperature had risen to 99°. A faint systolic murmur was heard over the heart; the paralysis was the same as the day before. Now, finding him in this condition after having obtained all the benefit that we probably could obtain from active purgation alone, and observing that he was a vigorous man with a tense pulse, I had twenty ounces of blood drawn from his arm. The croton oil was repeated. He was also placed upon one drop of aconite tincture every second hour. His urine was examined and found to contain a small amount of albumen.

On the evening of the day that he was so freely bled and purged his pulse was only 68 in the minute, and far less tense. This was on the 16th. Let us see how he has fared since.

Yesterday (17th) his evening temperature was 99°, and this morning it is 98.4°. His pulse, taken this morning, was only 72. His urine is still albuminous. He now answers our questions intelligently, and says that he feels quite well; he had a little headache early this morning, but none since. His tongue is still coated, and the face is drawn to the right. He can close both eyes. He has still left-sided hemiplegia. On examining his heart, I find that I can still perceive the very faint murmur heard the other day; it is followed by a distinct second sound. No swelling of the feet has been observed. His left arm is powerless; the leg can be moved more than it could the other day. The patellar tendon reflex and the ankle clonus appear completely abolished; but the man holds his leg so rigidly that I do not lay stress upon this as a matter of observation.

The reflexes in the arms are preserved. It is also very evident that sensation in both arm and leg is blunted, though not destroyed.

Here is a man paralyzed upon one side by an apoplectic seizure. The attack comes on suddenly, without premonition. There is no loss of consciousness; though he is somewhat dazed for a time, he regains consciousness soon; there is complete loss of power in the left arm, partial in the leg; and there is paralysis of the face on the left side also. There is slight murmur in the heart, a trace of albumen in the urine,—and this occurring in a man 60 years of age.

What has happened to this man?

Gentlemen, there can be no doubt that the sudden occurrence of the symptoms affords only two possible explanations: a cerebral clot or a cerebral embolus. Against embolism is this: there is not enough disease of the heart to give rise to it. Although you have recently seen a case of cerebral thrombosis without disease of the heart, yet we need not take this up for consideration in this case. He has slight thickening of the mitral valves, and possibly atheroma. The explanation here is found in a similar condition in the walls of the vessels in the brain, with slight rupture and extravasation. The question now is, Where was this lesion? The paralysis is incomplete in the leg, complete in the arm, partial in the face; there is also some sensory disturbance, but not absolute loss of sensation. The ordinary site of the lesion giving rise to motor disturbance is the corpus striatum. In this case the lesion would be in the right side of the brain. I do not think, however, that a lesion of the corpus striatum would give rise to an incomplete palsy of the face and leg and complete paralysis of the arm. I am inclined to believe that the cortical motor centre for the arm was the primary site of the hemorrhage, which subsequently extended over to adjoining centres. This explanation is rendered probable by recent advances in physiology; still, it is something we cannot be sure about. But there are several points of more interest to us than the exact site of the lesion. One of these is the cause. Why should this man have this rupture? He was not working hard; there was no special strain upon him at the time it occurred. Why did he have apoplexy? I think that we have an explanation here in the slight amount of albumen in the urine and slight disease of the heart, which point to the conclusion that there are also brittle blood-vessels in the brain; one of these has broken, causing effusion of blood.

An interesting point, here, is that the leg was not affected for some time after the arm was paralyzed. Turning now to the question of treatment, the first dose of croton oil gave him two large stools, the second only one watery movement. The effect of the bleeding was to reduce the tension of the pulse, and to make it slower. The leg also has greatly improved. Here is a case which was bled early, within twenty-four hours after the onset of the symptoms, and the result has been a favorable one. For one thing, we notice that there has been no secondary fever: whether this has been due to the bleeding, the purgation, or the aconite, it is certain from the temperature-record that there is no fever.

What shall now be done for him? We will keep up the aconite, and purge him occasionally, giving him only the blandest diet, and placing a blister at the back of his neck, and wait. Time will do a great deal towards the absorption of the clot and the restoration of function in these paralyzed limbs. After a while it will be a question whether electricity and massage may not be necessary for the restoration of the muscles, and soon iodide of potassium may be administered in order to favor absorption of the clot; but for the present there can be no doubt that the treatment he is on is the best one to pursue.

[The man, shown at a subsequent clinic, was seen to have made an excellent recovery, having very largely regained power in all the muscles.]

COCAINE AS A CARDIAC STIMULANT.

I shall now show you a case which I propose to discuss from a purely therapeutical point of view. The important questions which arose during the progress of the case, and in connection with the diagnosis of the disease and the pathology, are not the points which I wish to bring before you: I rather will call your attention to the results of treatment.

This man, 29 years of age, a laborer by occupation, was admitted into the hospital on the 15th of last month, suffering with typhoid fever. There is no doubt as to

diagnosis, or as to the fact that he was a very ill man. If you look at the temperature-record you will notice the temperature going up to 104°, and not only once, but a number of times is this high temperature attained. There were also noted great weakness of pulse, sweating, very feeble action of the heart, and tendency to pulmonary congestion.

This man was placed upon the usual treatment, mineral acids, quinine, and turpentine stupes, and just a few times oil of turpentine was given internally. From the outset he was very weak, and it was noticed that the ordinary stimulants seemed to have very little effect upon him; he used twelve ounces of whiskey daily without apparent benefit. During the progress of the case I was much struck with the weakness of the pulse and the whole condition of the patient. There was no congestion of the lungs, such as we often find in typhoid fever, and no local lesions to account for this, but he was suffering from the secondary effects of the typhoid-fever poison upon the circulation.

I then placed him upon cocaine hydrochlorate, a quarter of a grain every two hours, and subsequently half a grain at the same interval, and reduced the whiskey to eight ounces a day. Now, gentlemen, the improvement was striking; cocaine showed its power here, as it had in similar cases I have seen elsewhere, and in the hospital two years ago. I was prepared to find cocaine showing its power, as it did in this case in a most marked manner; and the patient, upon whom ordinary stimulants had very little effect, began to improve in the course of twelve hours after it was begun, and the cocaine was gradually reduced, and was stopped entirely last week. During all this time he was increasing in strength and the pulse in volume, and his general condition steadily improved. His temperature this morning is 99°, so that, although not yet normal, we regard the case as convalescent. The heart-sounds are far more distinct; the first sound, which was almost inaudible, can now be heard. The pulse has the same volume and strength as it had last night. His morning pulse is 74; last evening it was 72. It has never been a high pulse, however, being even at the height of the malady under 90, and in spite of the fact of the great weakness of the heart. There is vesicular respiration at the base of the right lung, with a few fine râles; percussion-note is clear, though less so than on the right side; the congestion has passed away.

He has stopped taking cocaine, and is taking a bitter tonic, and that is all that is necessary. It is to call your attention to the use of cocaine as a heart-tonic that I have brought this case before you.

While on this subject I thought you would be interested in looking at this temperature-chart,—that of a similar case. The patient to whom it belongs has left the hospital, though I expected to present him before you this morning. The man whose temperature you see recorded here was also ill with typhoid fever, in the same ward as the preceding case, for a month. He was even more ill than the other patient, since his temperature was 105°. There was the same extreme prostration and failure of stimulants to act upon the heart. The pulse was about 130, and was very weak; therefore it was not a slow pulse like the other case. The apex-beat of the heart was lacking in force, and the first sound was almost inaudible. He had also used quinine and mineral acid, and for a short period tincture of digitalis, but with perfectly negative results. Whiskey was likewise without effect. We gave him cocaine, one-quarter grain every two hours, then increased to one-half grain. The man's life hung in the balance for a few days; but then—really, I think, as the result of the cocaine—he grew more quiet, the nervous symptoms were favorably influenced, and the heart and pulse became decidedly stronger. He began on the 5th; the dose was increased to half a grain on the 6th: it was kept on at that rate until the 14th, when he had so manifestly improved that it was decreased to half a grain every four hours, and about a week afterwards it was gradually withdrawn altogether.

From the temperature-charts before us you see that these two cases go well together therapeutically. I bring them here in order to call your attention to cocaine as a heart-tonic in sustaining the circulation in low forms of fever; especially where there is cerebral disorder superadded. In typhoid fever these conditions are found, and I have just called to your notice the nervous symptoms in the cases before you.

Do not think, however, that these are the only cases in which I have resorted to the sustaining properties of cocaine. Indeed, I began nearly two years ago to

give it in cases of typhoid fever, and I have since often relied upon it to relieve low states of the system and weak heart. I have found in many instances that cocaine was of decided value.

You may ask, Is digitalis not indicated in such a case? It is, but some patients cannot take it at all, and in others it cannot be given for any length of time without causing symptoms of gastric disorder. Again, it has never seemed to me a good heart-tonic in cases of low fevers. Cocaine is free from the objections to digitalis. I could also give you the histories of a number of cases, illustrating the stimulating and sustaining powers of cocaine in cases of lowering of the powers of life, but this would be foreign to our subject. What I have said this morning may be sufficient to direct your attention to cocaine as a remedy of value in low fevers attended by nervous depression and a weak circulation.

ORIGINAL COMMUNICATIONS.

ON EPILEPTIC BRAINS.

Read before the Philadelphia Neurological Society, December 27, 1886,

BY FRANCIS X. DERCUM, M.D.,

Instructor in Nervous Diseases, University of Pennsylvania; Pathologist to the State Hospital for the Insane at Norristown.

THE writer has thus far had the opportunity of studying twelve epileptic brains. Eleven of these have been already described in the "Report of the Pathological Laboratory of the State Hospital for the Insane at Norristown" for the current year, while the twelfth has likewise been described in the Pathological Report of the same institution for the year 1885.* It is not, therefore, my intention to give a detailed account of the convolutions of these brains, but merely to point out some striking peculiarities and to give expression to some of the thoughts which this study has suggested.

We have, in the first place, a notable tendency to the confluence of fissures, which is an acknowledged point indicating a low degree of cerebral development. This tendency is well marked in *every one* of the brains studied. In a number of instances the fissure of Rolando is confluent with the Sylvian fissure. In a number of others the Sylvian, interparietal, and parallel fissures are variously confluent. One of the most striking and most constant instances of confluence is observed in the fusion of the parieto-occipital with the interparietal. It occurs completely in *seven* of the brains studied, and imperfectly in two others.

This tendency to the confluence of fissures is of necessity accompanied by an absence or lessened development of the normal arching or bridging convolutions. For instance (as is well known), the upper end of the parieto-occipital fissure is normally separated from the interparietal by the first occipital convolution of Ecker, the so-called *pli de passage supérieure externe* of Gratiolet. In the instances where these fissures are confluent this *pli de passage* is either entirely absent or so imperfectly developed as not to emerge upon the general surface of the brain.

As a result of the confluence of fissures, appearances resembling the conditions found in the brains of monkeys are occasionally simulated. This, again, is notably the case where the parieto-occipital and interparietal fissures are confluent. In the majority of instances in which this confluence occurs the upper end of the parieto-occipital passes through the interparietal fissure, and terminates far beyond on the lateral surface, thus exactly reproducing the *external perpendicular fissure of the apes.* Occasionally this external perpendicular fissure is accompanied by a second fissure running in a parallel direction, and in one of the brains studied there were three such parallel external perpendicular fissures. It is probable that in these cases *one* of the fissures is homologous with the corresponding fissure in the apes, while the others are merely "*vegetative repetitions.*" †

Following the course of the external perpendicular fissure we come, in some instances, upon a well-marked Wernicke's fissure,—*i.e.*, a fissure running more or less perpendicularly and separating the occipital and temporal lobes. In one of the brains the external perpendicular fissure and the fissure of Wernicke are so well developed that the occipital lobe is, as it

* Also more fully in the Proceedings of the Pathological Society of Philadelphia for 1885.

† The reader is referred to a communication by Dr. A. J. Parker published in the Proceedings of the Academy of Natural Sciences of Philadelphia, 1878, in which the *principle of the "vegetative repetition"* of fissures and convolutions is pointed out.

were, almost lopped off from the rest of the brain.

In addition to such fissures as appear to be of purely morphological value, we have others which bear no analogies to the normal fissures of either man or the apes. Prominent among these are numbers of anomalous fissures on the occipital lobes, especially on the lateral surfaces. There is also a tendency in some of the brains to the formation of transverse or perpendicular fissures on the frontal lobes. In one instance there are three such fissures present. Again, various fissures connecting the parallel, Sylvian, interparietal, and central fissures must be placed in the same category. One anomalous fissure deserves especial mention. It is a short one-forked branch, passing from the Sylvian directly down into the temporal lobe. It cuts deeply through the first temporal convolution, and the gyrus surrounding it completely breaks up the anterior portion of the parallel fissure. Evidently these fissures have a special significance which differs widely from that of the abnormal fissures which have homologies with those of the brain. To this significance we will shortly recur.

In addition to the two classes of abnormal fissures, these brains present striking facts of the under- and over-development of various parts. For instance, one brain presents an enormous over-development of the cuneus. The latter is so large that, instead of being wedge-shaped and small, it constitutes an enormous block of tissue, which is bounded below by a calcarine fissure depressed beneath its usual level, and anteriorly by a parieto-occipital fissure which in one hemisphere runs upward at *right angles* with the calcarine and in the other actually *runs forward at an angle of one hundred and twenty degrees.* In the same brain the lateral surface of the occipital lobe is also much enlarged. The frontal lobes, on the contrary, are small, and the fissures constitute mere shallow depressions on the surface. Here, then, is an instance of enormous over-development in the occipital regions, with an absence of development in the frontal regions. In another brain the quadrate lobule is so enormously developed as to be the most conspicuous part of the mesial surface of the hemisphere. This over-development is also shared by the inferior parietal lobule. The cuneus, on the contrary, appears unusually small. The surface of the quadrate lobule is made extremely complex by a number of deep and intricate fissures. Again, in another brain we have a *pli de passage supérieure interne* developed up to the surface,—a convolution which, as a rule, is developed only in the apes. Further, the various normal fissures of these brains frequently pursue aberrant courses. The Sylvian, parallel, and interparietal fissures are frequently deflected from their average courses by the over- or under-development of the convolutions bounding them. The absence or small size of some of the arching convolutions are, again, conspicuous illustrations of under-development.

In summing up the above results, it is evident that we have, first, abnormal fissures which are purely morphological in their significance, and, secondly, abnormal fissures which are purely pathological in their meaning. To the category of the first belong those fissures whose homologues are found in the apes or monkeys, and of these the external perpendicular may be taken as a conspicuous example. To the category of the second belong those fissures in which no homologies can be demonstrated. In this connection it is interesting to note that in the majority of the cases studied sclerosis of the skull coexisted. In almost every instance there had been a powerful hinderance to the growth and development of the brain. It is probable, therefore, that these anomalous fissures are the result of mechanical causes,—*i.e.*, of growth within an unyielding and an abnormally small space. In the development of these epileptic brains, therefore, both pathological and morphological factors must have played a part. There can be no doubt, however, that the pathological factor must have predominated, and it seems, indeed, as though it must have been at the very bottom of the altered and aberrant growth of the brain, and as though the morphological factors were only the necessary incidentals of a lowered and unbalanced brain-growth. Certainly the various instances of the hypertrophy and of the under-development of parts admit of no other explanation.

The study of these brains is very suggestive in regard to the essential pathology of epilepsy. The cardinal feature of epilepsy is, beyond a doubt, a nerve-explosion;

and whether this be a sensory, a motor, or a psychic explosion does not in any way alter the case. Now, the nervous system is continually storing up force, or, what amounts to the same thing, its protoplasmic equivalent. In the normal condition force is emitted in a relatively gradual manner, and this gradual outflow is dependent upon the interaction of *all parts* of the nervous system. In other words, the entire nervous system is in a condition of equilibrium, and the action of any one part is restrained or inhibited by the action of all the other parts.* Now, in order that this equilibrium may be maintained under the usual strains to which the organism is subjected, the nervous system must have a certain structure, which is the average structure, and which we have learned to regard as the normal. Now, in these epileptic brains certain parts are absent or poorly developed, others again are developed largely in excess, and others still are aberrant and bizarre. Surely it is not going too far to infer that in such a brain the maintenance of equilibrium must be confined to relatively narrow boundaries. In the normal nervous system there must be a certain play or, if I may use the expression, a certain elasticity of equilibrium,—a certain facility of readjustment between the different parts,—by means of which a *stable* equilibrium is secured. In a nervous system, however, where the parts are irregularly developed and therefore badly adjusted, even slight strains may be sufficient to disturb the balance. The parts cannot yield to or play upon each other, readjustments cannot take place, and some portion of the engine being, as it were, detached, suddenly runs down,—*i.e.*, an epileptic explosion takes place.

The above inferences appear unavoidable, though the writer does not by any means wish to imply that all epileptic brains must have the flaring abnormalities of structure presented by the ones he has studied. These cases, however, were all confirmed epileptics, mostly epileptic dements; one suffered from epileptic mania, and another was an epileptic imbecile. They certainly point out the importance of making a detailed study of the convolutions in autopsies of all cases with a history of epilepsy.

* See "Facts and Deductions bearing on the Action of the Nervous System," by Francis X. Dercum, M.D., *Journal of Nervous and Mental Diseases*, November, 1886.

AN ANALYSIS OF THE OCULAR SYMPTOMS OBTAINABLE IN EPILEPSY IN THE MALE ADULT.

Read before the Philadelphia Neurological Society, December 27, 1886,

BY CHARLES A. OLIVER, M.D.,

Visiting Physician and Ophthalmologist to the State Hospital for the Insane, Norristown, Pennsylvania; Ophthalmic and Aural Surgeon to St. Mary's Hospital, Philadelphia.

THE clinical material for these observations was obtained at the State Hospital for the Insane at Norristown, Pennsylvania. The report embraces a study of all of the ophthalmic symptoms that could be gotten from fifty male adult epileptics, without reference to any past etiological factor or present mental condition. This method was pursued for several reasons, most prominent being—

First. A special form of symptomatic disease was taken in preference to any mental condition, because similar mental states may be present in the many and bizarre forms of nerve-lesion, masking and hiding the true significance of the objective symptoms peculiar to any one disease to such an extent as to render differentiation impossible.

Second. A definite variety of disease was chosen, so as to avoid obtaining mere percentages of the ophthalmoscopic signs (which, as a rule, have been limited to an arbitrary designation of the tint of the optic disk and the size of the retinal vessels) of the total number of cases occurring in one asylum,—practically giving, if at all correct, a *résumé* of the different varieties of optic-nerve color and retinal-vessel size of the gross amount of residents of that asylum: an answer which is liable to alter at any time through change of number of patients and character of mentality, or to be totally diverse from the results obtained by another observer placed in a different situation.

Third. A large percentage of similar cases was taken. This was done so that the different mental states which are seen during the course of any *one* disease might be united into a theoretical average case, which would represent a typical example of the physical and physiological conditions of that disease.

Fourth. Males were used. This is important, for, by exclusion of the female subject, any errors that might arise from additional ocular changes dependent upon

diseases which are peculiar to the sex are avoided.

It may be interesting to note that native American stock has been used. There is nothing absolutely important in this selection, because, by reason of many obvious causes, a true American type of man has not as yet been established among us; yet it was intentionally done, so that results obtained from subjects born on American soil could be contrasted and compared with statistics of foreign-born population, in order to see whether the data would exhibit any decided peculiarity in ratios.

OBSERVATIONS AND CONCLUSIONS.

First. Direct vision for form, as a rule, normal in both emmetropia and corrected ametropia.

Second. Accommodative action normal in due proportion to age and refractive error.

Third. Visual fields for form and color reduced to one-third to one-twentieth of normal areas.

Fourth. Visual fields for form and color regularly diminished, without any indentations or scotomata.

Fifth. Order of color-fields follows the regular physiological sequence, without transposition or reversion.

Sixth. Subnormal color-perception to a slight extent, as evidenced by faulty selection of delicate tints and shades containing low percentages of green and red.

Seventh. Pupils, as a rule, equal in size and alike in shape.

Eighth. Irides freely and equally mobile to light-stimulus, accommodation, and convergence.

Ninth. Extra-ocular motion intact in all directions. The presence of insufficiency of the interni in the majority of cases is readily explained by association with existing H + Ah, and probably has no relation to the epileptic condition.

Tenth. Optic disk superficially over-capillary, with a decided grayness in its deeper layers, showing a low grade of incipient optic-nerve degeneration.

Eleventh. Scleral ring rather more sharply cut and broader, especially to the temporal side of the disk, than in the healthy eye; this being probably due to a slight shrinkage of lowered nerve-tissue.

Twelfth. Fibre-layer of retina increased in thickness, as evidenced by dense and coarse massings of striation extending in all directions from the disk, these being more particularly marked in the superior and inferior portions of the eye-ground, even hiding the edges of the disk itself in many instances.

Thirteenth. Retinal vessels large in size and carrying rather dark-colored blood, this being more pronounced than usual with the veins.

Fourteenth. Retinal veins exceedingly tortuous, and in a few instances pulsating.

Fifteenth. Retinal arteries frequently wavy and sometimes tortuous, especially the temporal and macular twigs.

Sixteenth. Retinal lymph-channels visible in the majority of cases, particularly seen along the larger vascular distributions and at the vessel-entrance as glistening and yellowish-white opacities.

Seventeenth. No other visible changes of any significance throughout the eye-ground except a granular condition of the choroid in the macular region.

In addition, it may be mentioned that, as far as practicable, nearly all of the deep and superficial reflexes were obtained throughout the body. These, as a rule, were above normal, and presented some curious anomalies, which will be reserved for a later publication.

As was to be expected among this class of patients, many of the subjective signs were negative; but, withal, sufficient data have been produced to warrant proper conclusions in this direction. The results obtained from the study made of the visible ocular changes are of special value, and may be cited as of sufficient imporance to be useful in diagnosis.

Thanks are due to Drs. Charles A. Woodnutt and Henry Sykes, assistant resident-physicians, for good work and carefulness displayed throughout these researches.

THE EMOTIONAL FACTOR IN THE CAUSATION OF GLYCOSURIA.

BY M. S. FALLS, M.D.,
Washington, D.C.

IN presenting for special consideration this quite obscure etiological factor, I do so believing it to be by far the most frequently causative of all the long list of predisposing and exciting agencies which have been cited by various authors. The

essential lesion of diabetes is usually held to exist in the region of the medulla (or, to be more explicit, in the floor of the fourth ventricle), and necropsies have shown degenerative changes in the meninges or in the nervous substance proper, such as neoplastic formations or spicules of bone which cause irritation, this irritation acting in a similar manner to the well-known laboratory experiment of mechanical stimulation of the ventricular floor. We are told by writers upon the subject that long-continued mental worry and excitement is also productive of diabetes, but the mechanism remains obscure.

The effects of mental strain upon the system, when examined carefully, are seen to be characterized by cardiac derangement, embarrassed respiration, sweating, alternate pallor and flushing of the face, muscular tremors, incoördination of speech, and sometimes diuresis, all of which plainly show increased activity of these medullary centres. As all organs when in a state of functional activity are more or less congested, and as prolonged congestion leads to irritation, and this to inflammation, it may then be stated as a fundamental principle that long-continued increased or excessive activity of a part will lead to degenerative changes.

Simple gastritis or gastric catarrh due to irritating articles of diet is an example of this. Here we have the gastric membrane thrown into a state of undue activity and stimulated beyond its power of endurance. As a result of this strain the integrity of the organ suffers, and disease becomes established. So it is with the kidneys and other organs. Indeed, the old axiom of "burning the candle at both ends" applies to all parts of the economy. Starting with this self-evident fact, let us turn our attention to the nervous system and analyze the phenomena of nervous action. The nervous system, especially the cerebrum, receives more blood than any other system, plainly showing that this fluid is essential for the proper performance of its functions. Moreover, of all the organs in the economy none require a period of such long inactivity for rest as the brain, and to produce this result an anæmic condition is necessary. The heart, which is apparently in a state of motion continually, nevertheless receives some relief during the interval between its beats. Severe exercise, however, will so augment its action that the period of repose between diastole and systole is insufficient, and morbid changes occur. Now, as healthy mental activity depends largely on the nutrition of the brain, we must expect to find intellectual efforts attended with increased vascularity, and so we do. How frequently does insomnia follow prolonged mental work! How uniformly does somnolence attend manual labor! The cerebro-spinal system, which contains numerous nerve-centres, acts not as a whole, but as a part. If, for example, one set of muscles are to be thrown into contraction, the governing centre of this group is called into a state of activity, and remains so as long as the muscular power is required; when the work is accomplished the centre relapses into a state of quiescence, during which time recuperation takes place. Should, however, a certain group be unduly exercised or abused, then does the exciting centre become so exhausted that paralysis results. This is well exemplified in writer's palsy and hammerman's palsy.*

It is unnecessary to state in detail the twelve centres in the medulla oblongata; but as these centres are brought into action by involuntary impulses, it is easy to understand how they may become so exhausted as to lose their power. Add now the effects of powerful emotions, such as prolonged shame, fear, chagrin, and the sense of some stupendous ordeal, which emotions act upon these centres, and what is the result? The continual congestion leads to irritation of these centres, which are in such close relationship with the diabetic centre that the irritation is propagated by both continuity and contiguity of tissue; the diabetic centre is consequently subjected to this stimulus, and glycosuria results. In chloroform-narcosis the subject, in either the first or the second stage, exhibits great fear, and is subjected to violent emotions; when the anæsthesia wears off, grape-sugar has been detected in the urine. Hysterical women, when recovering from an attack, pass large quantities of limpid urine, which in some cases contains glucose. These illustrate the effects of emotions upon the centres.

In summing up, I think we should ascribe to the psychical element a more important *rôle* than it now holds. In de-

* See Philadelphia Medical Times, October 16, 1886.

fence of this argument I submit the following cases, trusting that they may not be without interest:

William N., æt. 22. This patient had been out of employment for some time, his means were exhausted, and, receiving many insults on account of his poverty, he became melancholic and despondent. Two years ago his attention was called to the profuse micturition, accompanied by great thirst and rapid loss of flesh. His previous health having been good, the suddenness of the attack led him to seek medical aid early. Diabetes was suspected, which suspicion was confirmed by the chemical test. The patient passed from my observation some months ago not improved.

G. S., æt. 24. This young man, of a strong and robust constitution, entered upon the study of the law. Being of a nervous temperament, the fear of the impending examination and the mortification of returning to his home unsuccessful preyed upon him, and for two years despondency held full possession. Prior to his examination for his degree, fears were entertained for his health, and when adverse returns were made he broke down completely. A few weeks later, diabetes manifested itself, and, upon advice, he has gone South in hopes of recovering his former health.

REVIEW OF RECENT WORK IN MEDICAL CHEMISTRY.

BY WILLIAM H. GREENE, M.D.

ON THE PRECIPITATE FORMED BY PICRIC ACID IN NORMAL URINE, AND ON A NEW REACTION OF CREATININE.

WHILE studying the application of the picric-acid test for the detection of albumen, M. Jaffé has investigated the precipitate occasioned by this reagent in normal urine. When normal urine is treated with a concentrated aqueous solution of picric acid the liquid remains clear at first, but in the course of an hour a small crystalline precipitate separates. The precipitation is more rapid if the acid is employed in the form of fine powder (about one gramme to a hundred and fifty cubic centimetres of urine), or if an alcoholic solution of picric acid is used, twenty cubic centimetres of a five-per-cent. solution for every hundred cubic centimetres of urine. In the last case the clear liquid soon deposits a voluminous precipitate, consisting of a net-work of long yellow needles; if the reaction be hastened by brisk agitation the deposit is a crystalline powder.

This precipitate may be separated by boiling with water into uric acid and a substance which crystallizes in yellow needles: the latter constitutes the greater part of the deposit, and is a compound of potassium picrate and creatinine picrate. The precipitation of uric acid is more complete than by hydrochloric acid, and the author suggests the application of the reaction to the estimation of uric acid as well as creatinine, but has not as yet obtained satisfactory results.

When a solution of creatinine is treated with aqueous picric acid and a few drops of dilute potassium and sodium hydroxide solutions, the liquid instantly assumes an intense red color even in the cold. The color varies with the concentration of the solution from orange-red to blood-red, and remains unaltered for hours unless an excess of alkali has been used, when exposure to light changes it to yellow; the same change is brought about in a few minutes by the addition of acetic or hydrochloric acid. This reaction is well marked when the dilution of the creatinine solution is in proportion of one to five thousand, and may be applied to the detection of that substance in human urine. Creatine does not produce the color until after long standing; glucose gives a similar red after very long standing or on heating; acetone is the only substance which yields in the cold with the picric acid and alkali a similar color, but this is a reddish yellow that would not be mistaken for the pure red produced by creatinine.

ON THE DETECTION OF DISSOLVED COLORING-MATTER OF BLOOD IN THE URINE.

Carl Rosenthal finds that Heller's test—a red precipitate after boiling with sodium hydroxide and standing—yields no results when the urine contains less than one part of blood in a thousand. By working with five hundred cubic centimetres of urine, the hæmine test is capable of detecting one-half per cent. of blood. Struve recommends that the urine should first be rendered alkaline, then treated with tannin solution and enough acetic acid to make the reaction decidedly acid, and the resulting precipitate dried and rubbed with ammonium chloride; by treating with cold acetic acid hæmine crystals may then be obtained. If the urine be rich in albumen the precipitate should be burned and

the ash tested for iron by potassium ferrocyanide.

ON THE FATE OF MORPHINE IN THE SYSTEM AND ITS DETECTION IN THE URINE.

Julius Donath has not succeeded in detecting morphine in the urine of a morphiomaniac who in forty-eight hours took one and a half grammes of morphine hypodermically. In one case, after the injection of thirty-six centigrammes, morphine-sulphuric acid was also sought with negative results. The minimum quantity of morphine that could be detected after addition to the urine was two-tenths part per thousand: the process consisted in treating a litre of urine with a little hydrochloric acid and evaporating to one hundred and fifty cubic centimetres, precipitating with iodide of potassium and mercury and decomposing the precipitate in water acidulated with hydrochloric acid by hydrogen sulphide; the solution was concentrated, neutralized with ammonia, and evaporated to dryness, the residue extracted with hot alcohol, the extract evaporated to dryness, redissolved in hot water containing a little hydrochloric acid, and the solution allowed to stand twenty-four hours after neutralization with ammonia; the morphine then crystallizes.

ON THE DETECTION OF CHLOROFORM AND CHLORAL HYDRATE IN COMPLEX MIXTURES.

Dr. Charles Luedeking, who was the chemical expert in the Maxwell murder case, has published the results of some experiments made to test the Ragsky method for the detection of chloroform. This method depends on the decomposition of chloroform vapor into chlorine and hydrochloric acid by passage through a red-hot tube. The experiments showed that "by the process of decomposition no substances are generated which would vitiate the tests for chloroform by the Ragsky method. Chloroform, when it has caused death by inhalation, can with certainty be detected in the body four weeks after death, and, notwithstanding its volatility, it is certainly retained in the viscera in large amount during this time."

Hildebert Baron Tiesenhausen has studied the application of the extraction-method used for alkaloids to the separation of chloral hydrate from animal mixtures. The best results were obtained by agitation with absolute ether and with ethyl acetate; light petroleum, chloroform, and benzine did not yield good results. Five milligrammes of chloral hydrate may readily be separated from seventy-five cubic centimetres of liquid by two agitations, but one milligramme could not be separated by repeated shakings. The author finds that the most delicate reaction for the detection of chloral is that of Hofmann, which depends on the formation of benzo-isonitril when an alcoholic solution of sodium hydroxide and aniline is warmed with chloral, the benzo-isonitril being recognized by its odor: one-sixty-thousandth of a gramme may be thus detected. Then comes the reaction with naphthol,—a deep-blue color by the action of strong potassium hydroxide solution and α or β naphthol,—which reveals the presence of one-twenty-four-thousandth of a gramme: this test is of special value in doubtful cases, for, so far as is known, chloroform is the only substance which responds to it, and the reaction with chloroform is owing to the decomposition of that body by the alkaline hydroxide. Tiesenhausen recommends agitation with ether for the separation of chloral from the contents of the stomach, enough chloral being often obtained in this manner to respond to the naphthol reaction. From blood and urine, however, the most satisfactory results are obtained by distillation. No chloral could be detected in either the lungs or brains of poisoned animals.

THE GASTRIC JUICE DURING DEFICIENT INGESTION OF CHLORIDES.

Von Mering and Cahn, having investigated the effect on the gastric juice of cutting off the supply of chlorides, have published the following conclusions. The secretion of pepsin is independent of that of hydrochloric acid, and continues though no hydrochloric acid be present in the juice. When the supply of chlorides is cut off the secretion of hydrochloric acid diminishes, and when it ceases altogether it is replaced by no other acid, the juice remaining neutral. These results refute the theory that hydrochloric acid is formed in the stomach by the action of other acids on chlorides. When there is a complete absence of hydrochloric acid the contents of the stomach still contain chlorides. As soon as an excess of chlorides is present in the organism an abundant secretion of hydrochloric acid begins.

ON THE POISONOUS ACTION OF POTASSIUM CHLORATE.

Fourcroy and Alyon considered that potassium chlorate gives up part of its oxygen when taken into the system, and since the experiments of Binz and Marchand this explanation has been generally accepted as accounting for the poisonous action of that compound. B. J. Stokvis contradicts this view, basing his opinion on experiments of his own, of W. C. Kimmyser, and of H. C. van Gorcom.

Kimmyser investigated the elimination of chlorate in his own urine and in that of dogs on which he had experimented. He determined the amount of chlorine directly, after fusion with sodium carbonate, and after combustion with potassium nitrate. He thus found that, of four grammes of sodium chlorate, there was eliminated unchanged in his own case 2.277 grammes; in the cases of three dogs, to which had been administered 1, 4, and 16 grammes respectively, he found 0.896, 3.618, and 13.53 grammes. On the days when the sodium chlorate was administered and the doses were given hypodermically, there was an increased excretion of chlorides, and usually also of urea; this increase is to be attributed not to a reduction of the chlorate, but to a drain on the system, for a corresponding decrease from the normal excretion of chlorides was noticed on the following days. In this respect the action of sodium chlorate is identical with that of sodium nitrate, as Kimmyser determined by experiments on dogs whose urine had been rendered free from chlorine by inanition: he therefore concludes that there is no proof of a reduction of the chlorates in the economy. The reduction is also denied by Stokvis, Isambert and Rabuteau, and Von Mering, whose results are in harmony with those of Kimmyser.

The small quantity of chlorate that is unaccounted for in the urine is to be credited to passage into the secretions, which takes place even after the ingestion of small doses, to the slow elimination, to reduction in the urine, and to experimental errors. Kimmyser finds that a one-per-cent. solution of sodium chlorate in urine suffers a reduction of twenty-four per cent. of the contained salt by standing twenty-four hours at 20° C.; the reduction does not take place at the freezing-point or in acid urine, and it is diminished when the urine has been previously boiled: Kimmyser considers it to depend on the beginning of putrefaction. He also regards the reduction by blood as owing to complicated putrefactive processes which occur only as the blood loses its vital properties. Methæmoglobin and hæmatin result in the latter case; and that the change does not take place in living blood was shown by the fact that the intravenous injection of sodium chlorate in dogs was followed by the appearance of albumen and sugar in the urine, but no methæmoglobin, which passes very readily from the blood to the urine in these animals. However, after repeated doses, inflammation of the kidneys is set up, and red corpuscles pass into the urine: these are the source of the methæmoglobin which has been repeatedly found in the urine in cases of poisoning by chlorate.

The poisonous action of potassium chlorate produces heart-failure, according to Jacobi, and this has been attributed by Leichtenstern to the direct influence of the potassium; it does not differ from the action of potassium sulphate or that of potassium chloride in corresponding doses. The authors named agree that toxic results follow only when the dose is large, the solution concentrated, or when repeated small doses on an empty stomach have resulted in the ingestion of a considerable quantity. Van Gorcom finds that sodium chlorate is not more poisonous than sodium chloride in corresponding doses, whether the administration be by the stomach or by intravenous injection.

ON THE PRESENCE OF IRON IN THE LIVER.

Investigations on the quantity of iron in the liver are of but little value when the organ contains blood. S. S. Zaleski has studied the problem after removing all the blood by washing out the vessels with a two-and-a-half per cent. solution of saccharose, by which the liver-cells are in no manner altered. While iron was found to be constantly present in the liver-tissue, its proportions varied very considerably. In all the morphological constituents of liver-tissue it occurs in combination with albuminates and with nuclëin. One of the nuclëin compounds gives the ordinary reactions of iron, while the others do not; of the latter, Zaleski has isolated a compound which he calls hepatin. In these compounds the iron is present in two, if

not in three, states: ferrous, ferric, and ferroso-ferric. Ferrous oxide was found in fifty-two per cent. of the livers examined. In forty per cent. the phosphoric acid present was not sufficient to combine with the iron.

SNAKE-POISON.

R. N. Wolfenden finds that the poisonous properties of cobra-venom are not owing to bacteria or any living organism, nor to any alkaloid or ptomaïne, nor to cobric acid, as was described by Blyth. The so-called cobric acid consists of crystals of calcium sulphate. The venom is sometimes faintly acid, sometimes neutral. The poisonous properties are due to the proteid constituents, which are: (1) Globulin, which is always present and kills by producing asphyxia. (2) Syntonin, which may be precipitated along with the globulin by magnesium sulphate. It passes through parchment-paper to a certain extent when submitted to dialysis, and the toxic action of the acid dialysates is caused by this proteid, not by cobric acid. Its action resembles that of the globulin, but is more feeble. (3) Serum-albumen, which causes paralysis. (4) Traces of hemialbumose in some specimens. Doubtful traces of peptone are considered as accidental.

The venom of the Indian viper contains neither toxic acid, alkaloid, nor any living organism. The poisonous constituents are: (1) globulin, which greatly preponderates; (2) a small proportion of serum-albumen; (3) a proteid which possesses many properties of an albumen. True peptones were not found, and the author considers that the substances described as peptones by Mitchell and Reichart in crotalus-, copperhead-, and moccasin-venoms are really albumoses.

A NEW REACTION FOR THE DETECTION OF SMALL QUANTITIES OF HYDROCYANIC ACID.

G. Cortmann has applied to the detection of hydrocyanic acid and the cyanides Playfair's reaction, which results in the formation of a nitroprusside, the latter being recognized by its reaction with sulphides. The liquid to be tested is mixed with a few drops of potassium nitrite solution, from two to four drops of ferric chloride solution, and dilute sulphuric acid sufficient to cause the brownish-yellow color of the basic iron salt to change to pure yellow. The mixture is then heated to incipient boiling, and, after cooling, is treated with a few drops of ammonia; the liquid is filtered, and the filtrate mixed with one or two drops of a very dilute solution of colorless ammonium sulphide. If hydrocyanic acid was present in the liquid, a beautiful violet color will at once appear, changing to blue, green, and yellow in the course of a few minutes. If only traces of hydrocyanic acid be present, the color is bluish green, and rapidly becomes yellowish. The limit of the reaction is placed at 1 : 312,500, ten cubic centimetres of liquid being used: it is consequently more delicate than the Prussian-blue reaction, but less so than the ammonium rhodanate test.

TRANSLATIONS.

THE TREATMENT OF SYPHILIS BY SUBCUTANEOUS INJECTIONS OF CALOMEL.—Scarenzio's treatment, it will be remembered, consists in the subcutaneous injections of calomel in suspension in glycerin (ten centigrammes of calomel for one gramme of glycerin). This treatment is said to be very efficacious, several injections under the skin, during the space of about four months, of forty centigrammes of calomel in all, being sufficient: it not only counteracts the accidents which appear in the evolution of the disease, but also prevents their return. M. Balzar, desiring to try this treatment at the Lourcine Hospital, but fearing the irritating action of glycerin and the great pain which it causes, was induced to seek for another medium for the calomel, and struck on vaseline oil.

Two subcutaneous injections of the pure oil were at first tried, which proved absolutely painless, and leaving after them neither irritation nor induration. A severe case of syphilis was chosen. The patient was a young woman, aged 19, who had been suffering from the disease for about five months and was in her sixth month of pregnancy. Large patches covered the labia majora and the posterior portion of the anal orifice; patches were also observed on the left tonsil; general roseola, with large macula; abundant papulo-squamous eruptions on the abdomen and the lower limbs, and general adenopathy. The patient had been submitted for some time to treatment which remained absolutely without effect,—namely,

two Dupuytren pills daily, and also two spoonfuls of syrup of iodide of iron. Compresses moistened with Van Swieten's liquor diluted with distilled water were applied to the vulva during the night; cauterizations with a one-twentieth solution of nitrate of silver, gargles of chlorate of potassium, and baths.

On the 4th of October a first injection of two and a half centigrammes of calomel in fifty centigrammes of vaseline oil were made in the back. The injection was in no way painful. The following days a soft tumefaction showed itself, and was slightly painful at the injected part.

On the 11th of October a fresh injection of five centigrammes of calomel was made in the lumbar region, and in a few days the tumefaction attained the volume of a hen's egg. At one time the formation of an abscess was feared; but at the end of about ten days the indurated tumefaction ceased to grow, and was followed by progressive diminution.

Now, during this period the cutaneous manifestations, which had been so rebellious to the former treatment, had diminished rapidly.

Already on the 25th of October the roseola, together with the large patches on the vulva, had disappeared; of the latter there remained but a dry macula of a violet color. The general state was excellent, and the pregnancy was following its normal course.

On the 18th of November the amelioration still continued, and the induration on the spot of injection had diminished to two-thirds of its original size.

Hæmatoscopic Researches on the Normal Proportion of Hæmoglobin.—M. Henocque made the following communication recently to the Paris Biological Society respecting the normal quantity of oxy-hæmoglobin in human beings and in different animals. This communication forms the most complete statistic that has been yet furnished on this point.

Among two hundred and eight human beings, the normal proportion was between thirteen and fourteen; five per cent. had been noted fifty times; the proportion of thirteen per cent. is more common among inhabitants of towns.

For monkeys the normal proportion (in Paris) is about thirteen per cent.; for dogs, fourteen per cent.; for guinea-pigs, fourteen per cent.; for domestic rabbits, ten per cent.; for pigeons, eight to twelve per cent.; for lizards, three to seven per cent.; for fish (gudgeon), three to four per cent.

Action of Sulphide of Carbon on the Animal Economy.—A few years since, Signor Tamassia called attention (*Canstatt's*, p. 420, 1881) to certain changes of an hæmatic order, and mentioned different symptoms (dyspnœa, hemorrhagic infarctus of the lungs) following acute intoxication with sulphide of carbon, owing to asphyxia, which he attributed to alteration of the blood-corpuscles. Schwalbe also stated in 1884 that he had produced melanæmia and melanosis in the different organs of rabbits by slow intoxication. The importance of this fact with regard to the pathological physiology of malarial pigment induced MM. Kiener and Engel* to satisfy themselves of the truth of the phenomena recorded. They therefore sought to ascertain whether there did not exist some connection between this pigmentation and the changes in the red corpuscles described by Signor Tamassia. They made experiments upon a number of rabbits which had been intoxicated in different ways. Poisoning which was induced by strong doses resulted, both preceding and after the death of the animal, in an alteration of corpuscles which consisted in changes of an amœboid character. But in chronic poisoning neither this alteration nor rapid disappearance of the corpuscle was observed. The urine never contained hæmoglobin. The malarial pigment described by Schwalbe was never present. MM. Kiener and Engel have constantly encountered, in cases of slow intoxication followed by death, an accumulation in certain organs of a particular kind of pigment, which was ferruginous and derived its coloring-matter from the blood. Finally, the exaggerated formation of this ferruginous pigment in the spleen, marrow, portal vein, liver, and other organs, added to the morphological alteration of the corpuscle during acute intoxication, warrants the belief that sulphide of carbon acts as an agent attacking the vitality of the red corpuscles, stimulating its physiological waste notwithstanding the absence of hæmoglobinuria and methæmoglobinuria. V.

EDITORIAL.

ON THE DEFINITION AND EXACT MEASUREMENT OF CURRENTS IN ELECTRO-THERAPY.

AT a recent meeting of the Biological Society of Paris, M. Vigouroux communicated a note on the dosage of currents in electro-therapy, in which he criticised the usual methods of indicating this. A few years ago, in order to give an idea of the force of a current the number and nature of the elements employed to produce it were stated,—that is to say, its electro-motive force. At present, currents are employed according to their intensity, which means the quantity of electricity passing in a given time. As this quantity may be very accurately determined in ampères, to define the current would seem a very easy matter; but this is readily seen to be illusory, at least so far as the appreciation of its physiological effects is concerned. Take, for example, two patients for whom authors advise a force of five milliampères. It is found, upon trial, that the electrical resistance in the two patients is very different. In order to obtain five milliampères, thirty-six Daniell elements may be required in one case and only twelve in another. Under these conditions, it cannot be said that the two patients have been electrized in the same degree. They have received the same quantity of electricity, as shown by the galvanometer, but this quantity was transmitted to them under an electric pressure three times as great in one case as in the other, and this the galvanometer did not show. Two currents having the same intensity are not, therefore, equivalent in their physiological action. The chemical and magnetic effects of a current depend entirely on the quantity of electricity; the thermic and mechanical effects depend both on the quantity and on the electro-motive force. Now, in the present state of science, it is impossible to say in what degree the action of the current upon the organism is due to its chemical or to its thermic and mechanical properties. Therefore quantity is as vague a guide as the electro-motive force. Moreover, a given electro-motive force may produce very different intensities, and this to such a degree as to render the application of this mode of valuation absolutely dangerous in patients having a feeble resistance. It is also observed that in order to obtain a given intensity recourse may be had to very different electro-motive forces. This gives rise to a double uncertainty, which cannot be avoided unless the resistance offered by the patient is known beforehand; and this, of course, is never the case. The only rational manner, therefore, of defining the currents is to specify both the electro-motive force and the intensity, according to the custom adopted in manufacturing industries. Although the whole question concerning the influence of these two factors of electric energy in regard to their physiological effects has yet to be resolved, the means to do this, the author thinks, are at hand. And in this connection it would be interesting to compare the respective value of the electro-motive force and the intensity in the usual operations in electro-therapy, as the above considerations concerning the galvanic current apply also to the other forms of electric discharge. Existing apparatus may be considered as the extremes, of which the intermediary is wanting: on the one hand we have machines with an enormous potential and minimum intensity, and on the other hand, batteries of feeble potential and relatively great intensity. The author also pointed out the advantages of a rational system of defining the current,

and made the following suggestions. The electro-motive force and the intensity of a current passing through a part of the body being given, the value of the resistance of this part is then obtainable by simple division. Moreover, on multiplying the electro-motive force by the intensity, the energy of the current is obtained in volt-ampères, or watts. It is to be remembered, however, that the sole indication of the energy is no test of the physiological value of the current. The reason is very simple: an energy represented by twenty watts may be either the product of twenty volts by one ampère or of forty volts by one-half an ampère, and so on. With an equal number of watts, it is clear that a current of great intensity and of feeble electro-motive force would have an action upon the organism altogether different from a current inversely constituted. The total value of the energy is not so important as the respective value of its factors. In order to determine in a rapid manner the intensity and the electro-motive force, the author makes use of the Deprez-d'Arsonval galvanometer, with vertical needle, which possesses the advantage in a medical point of view of being completely astatic. The scale is divided into $\frac{10}{1000}$ ampères, and has two hundred of these divisions. A special commutator is so arranged as to place at will the galvanometer in the circuit of the electrodes or in derivation. The instrument is graduated for fifty volts. In order to determine the resistance it is not even necessary to wait for the current to produce its full effect. But in such cases three readings should be made,—two for intensity and one for electro-motive force. The number of volts divided by half the sum of the $\frac{10}{1000}$ ampères will give the resistance quite as accurately as more laborious methods.

THE MEDICAL REGISTER is a new weekly medical journal, edited by Drs. John V. Shoemaker and Wm. C. Wile, to be published in Philadelphia, the first issue of which will appear February 8. If it is not an aggressive and progressive medical journal, it will disappoint expectations.

THE RELATION BETWEEN THE FUNCTION OF GLYCOGENESIS AND ANIMAL MOVEMENTS AND CALORIFICATION.

AT a recent meeting of the Académie des Sciences, M. Chauveau made a further communication concerning his researches upon the hepatic functions and upon the active part played by glucose and glycogen in the production of motion and heat in animals. The glucose which disappears in the capillaries reappears and combines with the oxygen in order to be transformed into water and carbonic acid in the midst of the tissues, and this is the case in all the organs, including the muscles. But as regards the latter there is a supplementary act performed: they are insured from possible insufficiency of the combustible—that is to say, of glucose—by the store of glycogen which they themselves contain. This provision, which may be compared to that of accumulators in electricity, is made during the repose of the muscles. Only a part of the glucose then which disappears in the capillaries is directly given up for combustion; the other part, on losing its water, is transformed into muscular glycogen,—that is to say, into reserve combustible. The oxygen employed in organic combustion is especially taken up by the carbon of the glucose.

After demonstrating the important part played by the glucose of the blood in the production of heat and action, M. Chauveau concludes that no new impulsion, and consequently no mechanical action, can take place in the animal economy without the actual participation of the hepatic gland. The liver is the indirect collaborator of the muscles in the execution of movements: it becomes more active as a glucose-producer whenever muscular effort is going on in any part of the economy. As long as the hepatic cells furnish glucose to the blood in sufficient quantity, the animal continues to generate

the necessary quantity of heat for the working of the organs and for keeping up the temperature of the body. Let this glycogenic function relax and the glucose disappear from the blood of the vessels, then organic combustion will rapidly languish, and death will take place from arrest of calorification. The latter conclusion is justified by what takes place in animals submitted to prolonged abstinence: as the temperature decreases on the approach of death, the sugar disappears from the blood as well as from the lymph. If the animals die without decrease of temperature, glucose may still be found in these fluids.

FLOATING LIVER.

AMONG a number of interesting and instructive specimens shown at the last meeting of the Philadelphia Pathological Society was a floating liver, removed post mortem by Dr. Formad from a patient of Dr. Keen's. The condition is one of great rarity, and we do not remember any reference to the subject in the Transactions of our Societies. The patient was a German woman who had borne many children and had had for years a pendulous abdomen with great relaxation of the skin and separation of the recti muscles. The liver was very freely movable, and the dragging pains were a source of great discomfort. Dr. Keen proposed, for the relief of the distressing symptoms, to remove some of the redundant abdominal wall and fix, if possible, the liver; but meanwhile the patient died suddenly of renal disease. The ligaments of the liver were much relaxed, particularly the suspensory band, which was greatly elongated. The organ was not enlarged, and appeared healthy. It is to be hoped that Dr. Keen will give the profession a detailed account of this case.

The occurrence of floating liver is doubted by some writers. Legg a few years ago reviewed the recorded cases and came to the conclusion that the condition was not well established. Recently, however, the subject has been elaborately studied by Landau, of Berlin, to whom we are indebted for the valuable monograph on floating kidney. This writer claims that it is a much more common affection than hitherto supposed, and gives notes of sixteen cases. Thirty-one instances are reported in literature,—twenty-seven in women and four in men. The most common cause is a relative increase in the capacity of the abdomen, due to umbilical hernia, prolapse of the uterus, or, what is more common, an absolute increase associated with the so-called pendulous belly. The symptoms are indefinite, and consist chiefly of radiating pains in the upper part of the abdomen, particularly on the right side, dyspepsia, constipation, and venous congestion of genitals and rectum. In many instances the distress is very great: some women are relieved only in the later months of pregnancy, when the uterus acts as a support to the liver. The diagnosis rests upon absence of liver-dulness in the normal position and the detection of a large movable mass in the abdomen which has the form and outline of the liver. The examination in a recumbent posture frequently causes the condition to be overlooked. A point to which the writer does not refer is the possibility of mistaking a large spleen for a floating liver. Such an instance was brought to our notice a few years ago. There was in the recumbent position no liver-dulness, and the abdominal cavity was occupied by a large movable mass, but a careful inspection in the erect posture showed a narrow strip of liver-dulness in the normal position, and the tumor proved to be an enormously enlarged and very movable spleen, which, when the patient was lying down, pushed up the intestines and so obliterated the liver-dulness.

The relief of the condition is effected

chiefly by measures directed against the pendulous abdomen. Douches, friction, and electricity aid in establishing the contractility of the muscles, but the greatest benefit is obtained from a properly-constructed abdominal bandage. So far as we know, operative procedures have not been required.

ATAXIC ARTHRITIS.

THE obscure affection of the joints sometimes met with in cases of locomotor ataxia, and which is generally described under the name of "Charcot's disease," was recently under discussion before the Berlin Medical Society, and was made the subject of a singularly lucid discourse by Professor Virchow. The veteran pathologist seems still to be *facile princeps* in the science to the development of which he contributed so greatly, in spite of his more recent coquetting with politics and state-craft. Virchow is of opinion that the changes in the joints in the ataxic arthropathy do not differ essentially from the local changes in arthritis deformans, or so-called rheumatic gout. In the latter, he says, the first changes begin in the articular cartilage, and the other pathological alterations occur subsequently; and although there are usually no clinical evidences of inflammation of the joints, the process is undoubtedly inflammatory. The cartilage is thickened in spots, the cells being enlarged and often greatly increased in number. Then follows the peculiar stage of cleavage, when the swollen parts separate into layers. Afterwards come fatty degeneration of the proliferated cells, absorption of the cartilage, and exposure of the bone, resulting in an eburnation of the osseous surface. The atrophy of the cartilage is secondary, not primary; it constitutes the retrogressive stage of a previous proliferating process.

In the joint-affections of tabes dorsalis the processes are similar, although more rapid and marked in effect. The changes are more intense in degree and greater in extent.

If the question is asked, continues Virchow, What is the cause of such great alterations? one cannot doubt perhaps that in locomotor ataxia the nervous supply causes a deteriorated nutrition of bone, and that the badly-nourished bone more readily succumbs to inimical influences than healthy bone would. But when one attempts to explain a local morbid process confined to a single joint, as arising from a general spinal disease, one meets with a difficulty. A local cause is necessary for the production of the joint-disease. On account of the predisposition produced by the deteriorated nutrition, the local cause acts with more intensity than in other cases.

The early occurrence of joint-diseases in some cases of locomotor ataxia raises the suspicion that changes due to some other cause may have begun in the joint before the spinal disease began. Syphilis, for example, sometimes produces joint-affections which may be confounded with the joint-troubles of locomotor ataxia.

The ataxic arthropathy is, according to Virchow, not an essential part of the tabetic process. This may furnish the predisposition by deteriorating the nutrition of the bone; but some local cause is necessary to produce the local disease.

It is contrary to sound logic to attribute the disease in the joints altogether to the spinal sclerosis.

A JOURNAL OF BACTERIOLOGY.

THE prominence which the study of minute organisms as causes of disease has assumed in recent medical investigations has given rise to a demand for a special medium of intercourse between students of micrographic pathology.

To meet this demand, a well-known German medical publisher, Gustav Fischer, of Jena, has undertaken the publication

of a weekly, to be known as the *Centralblatt für Bacteriologie und Parasitenkunde.* The editor is Dr. O. Uhlworm, of Cassel, and the prominent collaborators are Professor Leuckart, Dr. Lœffler, and Dr. George M. Sternberg, U.S.A. Original articles will be printed in English, German, and French.

American bacteriologists are requested to send copies of original articles to Dr. George M. Sternberg at the Johns Hopkins University, Baltimore, in order that abstracts of the same may be promptly brought to the attention of specialists in this department throughout the world. Animal parasitology will also find a medium of publication in the *Centralblatt.*

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

THE Graduation-Thesis in Paris.—The thesis that is presented at the Paris School of Medicine and at the other faculties in France is very often a paper of real scientific value, for many reasons: first of all, the candidate for the diploma is required to sustain his thesis in public before a jury of four professors, who ask him—or her, for Paris is liberal enough to admit the women—some very searching questions as to why he failed to treat on such and such a point of the subject written on, and what he knows about it. Given the fact that the Professor has the right to refuse the thesis and refer the poor student to his studies for a period of three months, it becomes very inconvenient if one is not thoroughly posted on all the points of the subject he undertakes to write upon. Again, the thesis must be a printed one, and each candidate has to present to the faculty one hundred and sixty-three copies of it printed in clear type at his own expense. These copies must be delivered to the faculty four days before the student is called up to discuss its points with the jury of professors, and long before this eventful day he must have already presented a manuscript of the thesis to the faculty for their acceptance and for the purpose of having a president of thesis named. This is one of the professors, and after he has examined the thesis permission to print is given. The hundred and sixty-three copies of the thesis are distributed among the faculties in France and those of other countries in exchange for copies of their published theses. We notice on the list almost all the faculties in Europe, including several in England, and even in Canada, but none in the United States of America! Is it owing to the kind of thesis that is made in America? Have our papers no value because they are not printed or otherwise publicly quoted? We do not believe so; but, as the subject would take us too far, we leave it to those who are more directly responsible for this state of things to answer.

To return to the French theses, all these formalities make them of considerable value. They are mostly made on some special subject, often taken from cases seen in the hospitals, which are very well worked up, and they usually give the latest developments in regard to the matter, with a full bibliographical and historical sketch, making in fact a most complete monograph of the subject. Certain prizes are given by the faculties every year for the best theses, and they are very often quoted in the clinical and other lectures given by the best professors in Europe. We have known of students who have passed all their technical examinations and then have taken a full year to prepare their thesis. Outside of the circulation spoken of, however, they are not so well known, and, as they present very often original matter, we shall from time to time draw on this storehouse of knowledge.

Among the latest ones are several on therapeutical subjects. One by M. A. Pignoret gives his ideas of the use of "Salicylate of Sodium in Acute Orchitis complicating Gonorrhœa." He states that Dr. E. Henderson, of London, was the first to write on this subject, in the *Lancet* (1882, page 1027). This author gave it in twenty-grain doses every hour with great success, and on the pain being relieved he stopped or reduced the dose. The present writer details a number of personal observations in which he used the remedy in the Paris hospitals, proving that it gives good results. He proceeds to give a full history of the malady, which is clever, but not new to your readers, and he sums up his conclusions as follows:

1st. In gonorrhœal orchitis, salicylate of sodium will bring about a diminution of pain in a few hours, and in a longer time it will cause its disappearance.

2d. It acts well above all in cases that have acute epididymitis.

3d. When the inflammation of the cord is intense, the remedy will fail.

4th. In the large number of cases treated, the resolution of the swelling commenced very much quicker than in cases submitted to other treatment, and in a week or ten days the cure was complete, leaving nothing but a slight induration.

5th. This medication, then, has the advantage of allowing the patient to get about within a day or two at most. It is simple,

harmless, and appears to be superior to all other forms of treatment in this complication.

Another thesis, by a M. G. C. Coremenos, is on the "Use of Naphthaline." He shows that it was employed long ago, in 1843, by Dupasquier, in doses of fifty centigrammes up to two grammes, given in syrup, in cases of pulmonary catarrh. Naphthaline is insoluble in water, and should be triturated for a long time with gum, when it may be given in teaspoonful doses three times a day. Its use as an expectorant is still continued, and outside of its rather disagreeable taste it is excellent for this purpose. It has also been employed as a remedy in skin-diseases, such as lepra vulgaris and psoriasis, and again as an antiseptic dressing. Mention has already been made in our letters of its employment as an intestinal antiseptic in typhoid fevers in the service of Professor Bouchard, in Paris, and it will be recollected that he claims that it is the least toxic of the intestinal antiseptics, being some sixteen times less so than iodoform. It has been used also with success in combination with powdered charcoal in chronic forms of diarrhœa, particularly in children, proving especially useful when there were intestinal parasites. The favorable action of naphthaline when fetid urine exists is shown by the writer of this thesis, and he advises its use in the powdered form, given in doses of one-half up to one gramme. As high as five grammes per day may be given, in doses of ten to twenty centigrammes of the drug mixed with equal parts of sugar and perfumed with a little mint. Naphthaline has also been employed lately made up in capsules of keratin, which would digest only in the intestines. The author sums up its virtues as follows:

1st. From our experiences with the lower forms of vegetations and parasites, naphthaline possesses the power of arresting the development of the inferior organisms.

2d. In the powdered form it is sixteen times less toxic than iodoform, and it is a much more powerful antiseptic.

3d. Taken internally, it possesses all the advantages of charcoal powder without any of its inconveniences.

4th. It has given most remarkable results in patients who suffered with fetid urine.

5th. It not only destroyed the microbes, but also the larger forms of intestinal parasites. It finally has a good use in agriculture.

Professor Peter has given up his didactic lectures at the Faculty, and is now a clinical professor at the Hôpital Necker. We will attempt to give a *résumé* of a late clinical lecture of his at the hospital, on "The Present Medical Doctrines compared with Clinical Facts," but it would be difficult indeed to transcribe his inimitable style, and his works must be read to appreciate his lectures fully. As usual, he is after the microbists with a sharp stick. After showing that Laennec had made a great stride with his discovery of auscultation, and that he inaugurated precision and analysis in diagnosis, then that Corvisart took up Avenbrugger's discovery of percussion and demonstrated the physical alterations in living matter, with all its signs and lesions, Dr. Peter said, "Then came pathological anatomy into our medical doctrines, with more exactness; next came histological pathology, and we thought with the cells that we had at last reached the bottom; but no, for along came the microbe, which was born of the doctrine of parasites. According to those who believe in this doctrine, the microbe is not the lesion, but it is the agent of it, and for these persons there are no longer any local diseases, but only general maladies. For instance, pneumonia is not a local lung-disease; it is a general malady of infectious character, caused by the pneumonococcus, which, getting into the organism, first causes a fever, and then the local lesion of the lungs. This pneumonococcus, it seems, can get into several organisms at once, and then there is an *epidemic* of pneumonia; and it can also walk out of an infected organism and invade another: this is *contagion*. Even Virchow, the founder of cellular pathology, who was opposed at first to the famous bacillus of his countryman, Koch, has also capitulated, and he now sees in disease only a war of the microbe against the cell, a sort of Liliputian pathology. Koch, on the other hand, is only half triumphant, because it is easy to show him that the morbid disorders are not at all proportional to the number of the bacilli, and he is forced to capitulate in his turn, and now takes refuge in an hypothesis that there is a ptomaine secreted by the bacillus, and that this last machine is what does all the harm. Pathology is dominated at present by pathogenesis, and this by bacteriology; every day they come to tell the medical public, who look on astonished, that such or such a disease, one after another, is manifestly of parasitic origin.

"It seems that there are bacteria that do all sorts of things: the capsuled kind in the saliva do good in the mouth, and do all the harm in the lungs, where they manufacture pneumonia; others create hyperthermia in typhoid fever and algidity in cholera: thus some blow hot, and others cold. They find altogether too much. It is a regular overflow. This reckless pathogenesis may be considered as a sort of intellectual gymnastics, good for the brain; but your regular doctor is necessarily a utilitarian. Finding himself always in presence of disease, he tries to apply these new scientific notions; for instance, injections into the lungs have been tried, without, however, thinking how irrational such a medication is, even according to their own theories; for if only one pneumonococcus is left untouched by the injec-

tion the disease must persist. We can only say in favor of this method that there have been no accidents: the patients have more vital resistance than they think,—that is all.

"It has also been proposed to use medical antisepsis, imitated from the surgical. It is a generous idea, but as chimerical as the rest of them; for surgical antisepsis is based on the idea that the patient is a healthy individual, but that he has an open wound, and that it may allow the germs of the air to enter the body and to infect the organism. But for the medical doctor the situation is not the same: he is in presence of an organism that is already invaded, by their own hypothesis, by a microbe; so the thing to do is not to prevent him from getting in, but to get him out.

"I do not need to insist on this point, for it is already well known that the practice of medical antisepsis is far from being encouraging in its results. The same may be said for the antirabic or antihydrophobic inoculations, which are as irrational in principle as they are inefficacious in reality. They have the pretension (which is contrary to facts) to prevent the ripening of a disease which is already in incubation. Vaccine matter has no such power over incubating smallpox. These inoculations are useless," [poor Pasteur!] "as France has seen, in the year that is now drawing to a close, a mortality from hydrophobia equal to that of other years: that is, thirty cases, of whom fourteen died after these inoculations and the other sixteen without.

"So you see what modern medicine has gained so far from their new doctrines. Now what does the clinic say? By clinic I mean the *history of the patient*, for we have to do with pneumonical *patients*, not with the pneumonia itself, not with infection, nor with the lesion, but with the *form of the fever*, mucous, inflammatory, or nervous. We have, above all, to do with those *morbid accidents* that come on in the course of disease, such as congestions, hemorrhages, fluxions, or gangrene, *and according to them to modify our medication*, which proves, if proof be needed, not only the inanity and inefficacy, but also the danger, of any single treatment, such as the microbicide medication. We have to treat the *morbid factor*, which we can modify and even suppress.

"The clinic must rest on an attentive examination of the patient, full details of his disease, and all its morbid elements, taking an account of his strength and exploring the nervous system from the cerebrum to the sympathetic, with its several plexuses; then the state of the digestion, respiration, and circulation. Pathogenesis is the romance of disease, but our clinic shall be the *special history of each patient.*"

New Incandescent Ophthalmoscope.— M. Giraud-Teulon has just presented to the Académie de Médecine a new instrument by which he substitutes a direct light for the usual lateral reflected one. All those who are engaged in ophthalmoscopy know how difficult it is for students at first to get accustomed to reflecting the lateral light directly into the eye with the mirror used, and it has prevented many from making use of this means of diagnosis for a long time. The necessity of making the incident ray of light thrown by the right hand, armed with the mirror, concord with the emerging ray coming from the eye under observation, and the fact that this last ray must be received exactly on the proper lens of the ophthalmoscope, has also kept too many from this precious study of living pathological anatomy. To facilitate this, M. Giraud-Teulon proposes to use a direct ray of light, instead of the reflected one that has been so far indispensable. The present form of the ophthalmoscope is based on the principle that the emerging ray of light coming from the observed eye must follow the same track as the ray of light thrown, and therefore one of these rays must be deviated from the line of vision, and in the monocular methods this is the incident ray; but in the binocular system it is quite different, for here the emerging ray is received on a surface common to two rhomboids joined at the summit and divided between the two eyes. It gives two equal rays, sent right and left, following the parallel axis of the observed eye. This division, made by the instrument itself, gets over the difficulty, and the only remaining trouble is to find a position for the lighting focus so that it will not intercept the incidence of the inverse rays on the rhomboids. This is done by making a hole in the back of each of the rhomboids, about four to five millimetres in diameter, and just behind them is placed a small incandescent Edison lamp, which is worked by a Trouvé battery of three elements with the use of bichromate of potassium. The operator takes the whole instrument in his hand and places it before his eyes, as he would a mask used at a fancy ball. He has only then to press the button of the electric battery and *look*. Besides the absence of all technical difficulties, this new ophthalmoscope permits the observer to use the upright method, as he may come close up to the patient with his light.

New French Medical Laws.—There are two bills now pending before the *Chambre des Députés* to alter the present laws relating to the practice of medicine. One of the bills, called the *Projet du Gouvernement*, will most likely shortly pass. Some of its articles are interesting. As regards foreigners, one has already been put in practice for several years past,—that is, the government has referred the applications of foreigners who wished to practise here to the medical faculty, and

they have insisted upon all applicants passing *all the examinations first.* Article 2 of the new law says, "All physicians graduated elsewhere, no matter what their nationality may be, cannot practise medicine in France except on condition that they pass all the examinations before a French faculty" (eleven in all).

This in effect bars out any foreigners who would wish to settle in France, as there are few physicians who would like to start all over again and devote several years to botany and zoology, physics, etc., before reaching the practical examination, of which they might not be afraid. Art. 17 says, "All illegal practice of medicine will be punished by a fine of one to two thousand francs, and it can be increased by an imprisonment of six months to two years."

Art. 14. "The practice of pharmacy and medicine simultaneously is forbidden, even in the case of a person who may hold both the diplomas (pharmacy and medicine); however, any doctor who practises in a locality where there is no druggist within four miles may keep medicines under certain conditions."

Art. 6 interests the dentists, and so far the American dentists have enjoyed the cream of the practice in France, mostly in Paris; but they will have to hurry now, as the new law will be very stringent. So far, any one can practise dentistry here, and this has led to that interesting profession being a very low trade. Indeed, except for the impulse given to it by the Americans it might have remained so; but this, aided by several deaths that have occurred from the administration of anæsthetics by incompetent dentists, has started quite a reaction; but we regret to see that it is not in favor of the two excellent dental schools that have been established here this last few years, and which have several professors of American origin. Now the government insists, by the new law, that the dentists shall be doctors, but has not as yet provided any means of their acquiring their dental knowledge; indeed, it would be difficult for them to get it, as they have no dental professors. Art. 6 of the new law says, "The exercise of the profession of dentist is forbidden to all persons who do not hold the diploma of doctor of medicine, or at least that of *officier de santé*, both of which must be obtained by passing the examinations before the Faculty of Medicine."

The degree of *officier de santé*, which is the second class of the doctorate in France, is a good deal inferior to that of doctor, but it is almost as difficult to get, as the examinations consist of seven in all, and go over all of medicine and surgery, as well as anatomy, physiology, etc. The principal difference is that the candidate is not compelled to have the degree of doctor of arts and sciences first of all, as the doctor is. The *officier de santé* is not allowed to do surgical or obstetrical operations unless assisted by a doctor, and he cannot act as legal medical expert in the courts, nor as hospital physician, but otherwise he is a regular practitioner. Still, we cannot see how the dentist of the future is to be taught his special art by passing medical examinations, unless the Paris Faculty intend to send over to the United States for a few experts to make a corps of dental professors. The new law in relation to dentists continues: "Those who may be practising dentistry when this law is promulgated, and who are over thirty years of age, will be allowed to continue if they have practised two years; but they will not be allowed to use anæsthetics unless assisted by a doctor."

Treatment of Whooping-Cough.—A Norwegian doctor, H. J. Vetlesen, of Hamar, gives some hundred and sixteen cases of whooping-cough in which he obtained favorable results in over seventy-one per cent. of the cases, and entire cures in twenty-five per cent., with the use of the following mixture:

℞ Ext. cannabis indicæ, 1 gramme;
Ext. belladonnæ, 50 centigrammes;
Alcoholis (at 90°), 5 grammes;
Glycerini, 5 grammes. M.

S. Give four to twenty drops morning and evening, according to the age of the child.

Dr. Vetlesen tried the extracts separately, but could not obtain the same results as when they were combined as above.

Changes at the Paris Faculty.—M. Farabeuf, who for so many years has been the *chef* of the dissection pavilions, has just been elected a full Professor of Anatomy in the place of M. Sappey, retired on account of limit of age. According to the new law, all professors are shelved on their reaching seventy, but an exception is made for those who are also members of the Académie des Sciences. M. Sappey was not of this number; since his retirement, however, he has been elected a member of that august body. M. Gariel has been chosen Professor of Physics in place of M. Gavarret, who was also retired on account of reaching the limit of age. M. Gariel is one of those who has done so much to get physicians to adopt a more exact method in applying electricity by measure (milliampères) in place of the old and uncertain method of the strong and weak currents.

Professor Farabeuf informs us that his work on anatomy will be out before long, and that it will contain over two thousand wood-cuts. He is a very popular teacher, and does not believe that nature can be reproduced in anatomical drawings so that students can understand it: so he has a most wonderful collection of schematic drawings and wooden models for teaching purposes. He uses the plainest kind of language in his lectures, and last week he even went so far as to take his coat off to

show how certain manipulations were to be done on the bony pelvis. Coming after M. Sappey, who was the pink of propriety in everything, always appearing in a dress-coat buttoned up to his neck in his lectures, the change is very marked; but, like some of our American lecturers, M. Farabeuf is very popular with the students.

There are two obstetrical professors at the Paris school: one in charge of the Maternity Hospital, Professor Tarnier, and the second one is Professor Pajot, who for many years has been at the *Maison d'Accouchement;* his many interesting and practical lectures have served to teach thousands of accoucheurs and *sage-femmes* their profession. But he also now leaves the Faculty, for he attained the age of seventy on the 18th instant, when he voluntarily retired, as he did not wish to be forced to give up. The new rule seems hard sometimes, that a hale, vigorous man such as Professor Pajot should be forced to retire in the plenitude of his powers; but something must be said for the hard-working assistant-professors, who have rarely ever become full professors until they were what we would call old already. Professors Farabeuf and Gariel, the newly-elected professors, have both been working many years, and they are to-day both gray-headed men of about fifty: so some excuse must be made for the cry of "Make room!" and the speeding of the older men into retirement. A fine bust of Professor Pajot was uncovered at his last lecture, and speeches were delivered in his honor. It is supposed that Professor (*agrégé*) Pinard will get his place, and that M. Dieulafoy will take that of Professor Hardy, who retired last summer.

The faster, Merlatti, went to the end of his fifty days, but his medical committee withdrew after the forty-fifth day, so that the rest of the experiment is very uncertain, to say the least of it, as it then degenerated into a sort of show where people were admitted at from twenty cents upward. The case is, however, a very curious one, as the man certainly fasted for the forty-five days, if not for fifty; but, as before stated, the results for science are not of much importance.

It may interest some of your readers to know that the new volume of clinical lectures by Professor Jaccoud, from which you published one on "Gonorrhœal Infection," is now published by the editors, MM. A. Delahaye and Lecrosnier.

THOMAS LINN, M.D.

PARIS, December 27, 1886.

BOSTON.

THE vital statistics of Boston for the year 1886 have been published by the city registrar, and from his report it appears that the total deaths amounted to nine thousand two hundred and sixty-three, which is less by three hundred and fifty-nine than the deaths for 1885. The death-rate was 23.29 per thousand of estimated population,—a little less than our average for the past twenty or thirty years, which has been twenty-four per thousand. While the number of decedents under five years of age was, as might be expected, less in 1886 than in 1885 by eighty-three, yet it is singular to note that the deaths under one year of age were greater by one hundred and forty-four in 1886 than in 1885. Phthisis caused one thousand and ninety-two deaths during the past year, being 18.27 per cent. of the whole mortality. This proportion is the largest for the past twelve years. Pneumonia caused seven hundred and seventy deaths, two hundred and thirty-nine less than in 1885; diseases of the heart, five hundred and sixty-eight deaths; diarrhœal diseases, seven hundred and eighteen; croup and diphtheria, four hundred and seventy-seven. These were nearly the same as for the preceding year. The suicides were forty-four, against forty-five in 1885, and the homicides thirteen, an increase of four.

The Harvard Medical School has received a unique legacy, consisting of the mortal remains of Mr. Isaac W. Sprague, who has been in the show-business as a "living skeleton" for a number of years past. He was said to have weighed twelve pounds at birth, and to have developed naturally till the age of twelve years. He then began to emaciate, and continued to lose flesh to a most extreme degree. He married at twenty-six, and was the father of three healthy children. For many years the atrophy of the muscular system has been so marked as entirely to prevent locomotion. When his professional engagements brought him to any of the dime museums of Boston, it was his habit to arrange with Dr. O. W. Holmes, for so many years Professor of Anatomy at the Harvard School, to exhibit himself in the amphitheatre. These exhibitions afforded a very pretty display of the osseous and ligamentous systems, with a certain amount of physiological action added to the demonstration. While of course fully alive to the humor of the occasion, Dr. Holmes always had the thoughtfulness to remind his audiences in advance that Mr. Sprague was not a mere anatomical demonstration, but a sentient human being. The séances usually closed with a collection, and to the mutual satisfaction of all concerned. Mr. Sprague weighed forty pounds at his death. Many of our leading physicians had examined him with a view to diagnosis, but without expressing positive opinions. It is now possible that an autopsy may explain the cause of his mal-nutrition.

During the last two months the druggists, as well as many other shopkeepers, have been suffering from one of the periodical attempts to secure the enforcement of the Sunday laws of our statute-books, an attempt made perhaps with more desire to make these laws unpopu-

lar than in the interest of the preservation of the day of rest. Druggists were notified that they would be prosecuted if they sold anything but medicines on Sunday, and accordingly they waived the trade in cigars and fancy articles which formed a considerable part of their Sunday profits. Even thus a few were complained of, and the Committee of the Druggists' Association advised an absolute closure and cessation of all business, ostensibly as the only means of avoiding prosecutions, but probably as a method of bringing public sentiment to terms by depriving the community of medicines. Some little embarrassment was occasioned to medical practitioners for a Sunday or two, but now the shops have settled down to the practice of keeping their doors locked, but opening promptly when the bell is rung and dispensing medicines, whether called for on physicians' prescriptions or on lay orders; but refusing, at least when there is a chance of detection, to sell anything outside of medicaments.

The meeting of the Suffolk District Medical Society in the Section for Clinical Medicine, Pathology, and Hygiene on January 12 was occupied by a very interesting discussion on the subject of poisoning by arsenical wall-papers. An attempt was made to obtain a law from the last Legislature prohibiting the manufacture of wall-paper containing over one-fifth of a grain of arsenic per square yard, but the effort failed through the opposition of the manufacturers and dealers, and perhaps through the lack of unanimity of the petitioners and the narrowing of the scope of the original bill to wall-papers while other papers and textiles were not guarded against. At the meeting in question, Dr. J. R. Chadwick opened the discussion with an account of the poisoning of two or three members of his family in London, a few years ago, by heavily-loaded arsenical paper. In the fall of 1885 he had a paper put upon his nursery, bought from a leading dealer of this city, and certified to have been analyzed and to be free from arsenic. The appearance of symptoms of irritation of the mucous surfaces, colicky pains, gastric and intestinal disturbance, etc., followed so closely upon occupation of this room, and ameliorated so promptly on removal from it, that the paper was finally suspected, in spite of the assurance of the seller, and on being analyzed showed a large amount of arsenic.

Other clinical evidence was offered at the meeting, from Drs. C. E. Stedman and Edward Wigglesworth, of arsenical poisoning in members of their own families traceable to this source. Professor Lyon, of Harvard College, and Rev. Dr. Young, of Cambridge, narrated personal experiences of themselves and their families in this same direction. Arsenic was found in the urine of one of the patients during the continuance of the symptoms, and later was found to have disappeared. Professor Lyon, who has taken great interest in this subject and has collected some thirty cases of poisoning from arsenical papers, stated that a year ago fifty per cent. of the papers analyzed contained over one-fourth grain of arsenic per square yard.

Dr. W. B. Hills, of the Harvard Medical School, who has made analyses for some of the manufacturers and dealers for several years, stated that from his analyses in the years 1879–83 from fifty-four to sixty-five per cent. of all papers were arsenical, thirty-one to thirty-five per cent. strongly so. In 1884 there began to be less arsenic used,—forty-seven per cent. only of the papers containing it at all, and but twenty-two per cent. a large amount. In 1885 he made no analyses. In 1886 thirty-three per cent. were found arsenical, and but thirteen per cent. strongly so. Hence he concluded that the question was solving itself under the pressure of public opinion, and that perhaps legislation was unnecessary.

Mr. Tennent Lee, a chemist, admitted the presence of arsenic in wall-papers, but denied the possibility of its affecting the occupants of the rooms. He thought the alleged symptoms were indistinguishable from those of sewer-gas poisoning, foul furnace-chambers, and even from nervous exhaustion and disordered imagination. In answer to a question, he admitted that none of these other causes could account for the presence of arsenic in the urine.

Professor Carmichael, of Bowdoin College, said that in some one hundred and fifty analyses that he had made of cheaper grades of paper in use in country districts in Maine, he had found that most of the papers costing from six to eight or ten cents a roll contained arsenic, averaging two and one-tenth grains per square yard. He thought, however, that any legislation should take into account the form in which arsenic existed in the paper,—arseniate of iron, for instance, which existed in the so-called "beefsteak" papers, being quite indestructible and harmless to health.

Other chemists spoke on the subject. Dr. E. S. Wood, whose paper three or four years ago first directed public attention to this danger, said that he thought the mode in which arsenic gained entrance to the system was in the form of dust. On the tops of door-jambs and windows colored dust could often be collected which had gathered from wall-paper.

The meeting adopted unanimously a resolution offered by Dr. Chadwick, to the effect that arsenical wall-papers had produced the symptoms of arsenical poisoning in the occupants of rooms so papered.

It is quite evident that the discrimination between dangerous and safe arsenical papers cannot be simply a matter of the proportion of arsenic present, but that physical conditions must also be taken into consideration. C. F. W.

Boston, January 13, 1887.

PROCEEDINGS OF SOCIETIES.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

THURSDAY, JANUARY 9, 1887.

B. F. BAER, M.D., President, in the chair.

THE Secretary read the following paper, by Dr. H. H. WHITCOMB, of Norristown, Pennsylvania.

A REPORT OF SIX HUNDRED AND SIXTEEN CASES OF LABOR IN PRIVATE PRACTICE.

Up to March 31, 1886, I had attended six hundred and sixteen cases of obstetrics. I have had no death of a mother, and only two stillborn children; one of these was destroyed by craniotomy. The forceps have been used in two cases only. I have had no case of twins. I have had one case of elbow-presentation, one shoulder-, one hand-and-face-, and three breech-presentations; all the others were by the vertex. Placenta prævia was present in two cases at full term, and in two miscarriages, one at seven and one at five months. Puerperal convulsons occurred in two patients. A series of thirty-two cases of puerperal fever, but fortunately without a single death, followed me in the winter and spring of 1882. The first case occurred after I was in attendance on a case of scarlet fever, and was followed by three other cases; the next two or three obstetric patients escaped, when I was called to attend a woman who was confined while convalescent from erysipelas. The fever developed in her, and then every case I attended that winter and spring suffered with it. Consultation confirmed the diagnosis in all the cases. One instance was after a miscarriage at seven months following pneumonia. The patient had a tedious convalescence, but has since had a child weighing thirteen and a half pounds. I tried to stop attendance on this class of patients, but could not get rid of them. The epidemic ceased as suddenly as it commenced, and I have not had a case since. The smallest child delivered at full term weighed three pounds and lived only three days. Three deaths of infants have occurred from trismus, and four deaths, in children a few days old, for which I was unable to assign a cause. They simply moaned until they died, while they appeared to be in good condition. I had one case of hour-glass contraction, and four of severe post-partum hemorrhage at term. My success I ascribe to patient waiting and conservatism. I do as little meddling as possible, and do not use antiseptic injections. The credit is partly due to my old teacher, Professor Penrose, who is a safe guide to follow. I owe much to his careful instruction. I see so many doctors who, in almost every case of obstetrics they get, if they arrive before the child is born, put on the forceps to "hasten delivery and shorten the woman's suffering." I am very positive that this frequent use of the forceps is abuse. I have had a number, possibly twelve, of ruptured perineums; they were immediately stitched, with a perfect result in all cases. I have never had a vesico-vaginal fistule, though one of our teachers would impress his classes with the idea that these cases occur in the hands of the country practitioner. I might say the only cases I have ever seen were those in the care of the city doctors.

Dr. H. A. KELLY remarked that Dr. Whitcomb's report was full of interest, and in criticising the observer must be careful not to impose the rules and statistics of an average Philadelphia practice upon the Norristown people. While it is true that ailing, delicate women live and require obstetrical service in Norristown as elsewhere, yet it is a fact that in Philadelphia the up-town mill population from all over the civilized world, and the down-town population of pampered society women and alley-offscourings, present very different problems to the accoucheur.

With notable exceptions, labor in the country is *easier*. Differences of the same kind in greater degree exist between our native and foreign population. He was much struck with this fact last summer, when he went to the Anatomical Institute in Leipsic, to Herr Dornfelder, to buy a normal female pelvis. He was going to Berlin, to return in a month, and instructed him to find a pelvis as near a normal specimen in the museum as he could in the large amount of material passing weekly through the Institute. Upon his return he was given a specimen, which he now had in his office, which was the nearest to the normal Herr Dornfelder had been able to find; and he assured the speaker that a normal pelvis was rare. This dried pelvis, with artificial ligaments, measures: Sp. I., 25½ cm.; Cr. I., 29½ cm.; Cr., 9 cm.; Di., 13 cm. The argument as to different necessities in different localities holds good with regard to the use of antiseptics.

Dr. WILLIAM GOODELL read a paper entitled

A YEAR'S WORK IN OVARIOTOMY.

In it he stated that he had had during the past year fifty-nine laparotomies, but that, lest his paper should be too long, he should limit himself to the consideration of his ovariotomy cases. Of these he had had thirty-nine cases, with three deaths.

Of these deaths, one occurred on the table from the difficulties of the operation. It was a dreadful case of intra-ligamentous cyst with universal adhesions, from which it was shelled out without a pedicle. The ureter had to be dissected out for twelve inches, and the entire colon, womb, bladder, and small intestines were attached to the cyst. It was a very forlorn case from the start, and he operated merely from a sense of duty. He stated that

in the removal of intra-ligamentous cysts the ureter is in great danger, and he believed that it had been repeatedly torn across without the knowledge of the surgeon. Dr. Goodell stated that, before the death of this case, he had had in succession twenty-two successful cases, and afterwards a series of eight cures before the next death took place,—viz., thirty-one cases with one death. The second death was due to obstruction of the bowels in a case of large fibroid of the womb and ovarian cyst weighing sixteen pounds. On account of the fibroid, both ovaries were removed. He had had his share of cases of obstruction, but this was the first fatal one in his recollection. The remedies that he used were calomel and belladonna by the mouth, and turpentine by the rectum. The obstruction is due to the adhesion of a knuckle of intestine either to the stump of the pedicle, to the abdominal wound, or to some denuded surface. As soon as symptoms of obstruction presented themselves, he always aimed at once to open the bowels.

The third death occurred in a case of malignant cystic disease of both ovaries in which the operation was incomplete. Malignancy had been suspected, but the operation was forced on him on account of the excessive pain from which the woman suffered. Yet he argued, from his own experience and from that of Schroeder and Martin, that, other things being equal, it was always wise to remove ovarian cysts, even when malignant, for patients' lives would be greatly prolonged by the operation.

The right ovarian cyst had no pedicle, but ended in a brittle cancerous mass as large as his fist. This, with very great difficulty, was ligated *en masse*, and then bleeding vessels were secured separately. The left ovarian cyst was so fastened to the womb, pelvis, and broad ligament by masses of cancerous excrescences that he did not attempt to remove it. He would have abandoned the case after he discovered the nature of the complications, but he had gone too far to recede, for his hand had been inside of the right cyst to break up its septa, and blood was flowing profusely from it. The lady died twenty-six hours later, from shock and hemorrhage.

He stated that some ovariotomists do not report their incomplete operations or their exploratory incisions, but that he thought it fairer to do so. If his memory served him no trick, this was the only incomplete operation for ovarian cyst that he had ever had. None of his cases had been selected, and he had refused to operate in one case only, and that one on account of epithelial cancer of the cervix; so that he did not have any exploratory incisions to report. He had twenty-one cases with adhesions, a very large proportion, which he attributed to the tendency women in this country have of postponing the day of operation. He also had had twenty cases of double ovariotomy; but this large number was due to his rule of removing the second ovary in all malignant or suspicious cases, in all cases which have passed the climacteric, in all cases of incipient disease, and always when asked by the patient to do so. He further stated that he still adhered to Listerism, and that he used Keith's dressing of one part of carbolic acid to seven parts of glycerin.

Dr. PARISH cited a few instances of evil results following abdominal tapping for purposes of diagnosis or for relief from distention. In his first ovariotomy case, with the view of clinching the diagnosis, he aspirated and withdrew a few drachms of somewhat cloudy ovarian fluid. The patient presented some symptoms which in a few days became grave,—pain in the tumor, rigors, rapid and feeble pulse, and high temperature. He operated during the existence of these symptoms, and found suppuration of the interior of the cyst and extensive anterior adhesions; both conditions doubtless dependent upon the aspiration. The patient recovered.

A few years ago a well-known medical gentleman of this city aspirated a tumor supposed to be a multilocular ovarian cyst. Though the fluid was stated to verify the diagnosis, the patient miscarried in one or two days of twins at about the fifth month, and the tumor proved to be simply a uterus enlarged by reason of a multiple pregnancy.

He had recently seen in the Philadelphia Hospital a shocking case of labor, in which active labor-pains began one week previous to admission to the hospital. No urine had been voided for several days. Pregnancy was denied by the patient and her friends, and was not recognized by two physicians. The woman was small and deformed, and in the abdomen were two fluctuating tumors, one due to a distended bladder, the other the uterus. Aspiration was resorted to in both tumors, a procedure that was not only unnecessary for diagnostic purposes in this case, but which would probably have been highly detrimental to the patient had not the neglected and protracted labor already determined a rapidly fatal result. Though tapping for relief and especially for diagnosis is less frequently resorted to than was the case a few years ago, yet even now it is too frequently done.

In reference to the development of cancer or sarcoma after the removal of seemingly benign ovarian tumors, he had seen recently an example in a patient operated on by Dr. Hickman and himself. A large cyst of one ovary and a small one of the other, both free from the appearance of malignancy, were removed, and the patient made a tardy recovery. In about a year sarcomatous growths developed in the neck and axilla, and a large one in the abdominal wall of the left lumbar region. The patient died a few weeks ago, and the autopsy was made by Dr. Morris Longstreth, and though the sarcomas referred to

were present, there was not intrapelvic disease. An interesting feature was the total disappearance of the ligature of iron-dyed silk with which the pedicles and several vessels were secured about eighteen months previously.

Dr. H. A. KELLY stated that while simple tapping was often in no way injurious, it was also often productive of grave injury, and one of his own cases illustrated this point very well. The patient, having a cyst weighing one hundred pounds, was tapped in the left iliac region by a notorious homœopathic surgeon. She had previously suffered from pressure-symptoms. From now on she suffered from severe inflammatory pains around the puncture, and at the operation the extensive dense adhesions at this point constituted the chief difficulty. She is now well, more than a year since the operation.

It is a cause for mutual congratulations for American operators that their results are becoming so good. The whole credit of this lies in the thorough use of antiseptic agents and the rendering the field of operation completely *aseptic*.

He believed, too, that our cases at home are more difficult than those now being operated on abroad. The tumors we operate upon are older, and with the increasing age of an ovarian tumor occur many changes detrimental to the patient: depression of vitality from pressure-symptoms, diversion of so much albumen from the system at large, surcharge of the emunctories, as well as adhesions and unfavorable changes within the tumor itself.

Keith's dressing of a strong carbolized glycerin has rendered excellent results in the speaker's hands in at least twenty cases.

Dr. GOODELL, in answer to a question by Dr. Baer, said that he had operated during menstruation merely from pressure of time on the part of the patient, and little or no effect was produced on the discharge by the operation.

Dr. JOSEPH PRICE, in commenting upon some points alluded to in Dr. Goodell's paper fearing the contaminated atmosphere of a general hospital, cited the statistics of two hospitals,—special department of Birmingham General Hospital and Birmingham Hospital for Women,—covering a period from January, 1878, to September, 1885.

Special Department of General Hospital, ovariotomy, 35 cases, 11 deaths = 31.4 per cent.

Birmingham Hospital for Women, ovariotomy, 268 cases, 19 deaths = 7.1 per cent.

During the same period the total number of extra-abdominal operations in the Special Department of General Hospital: 85 cases, with 21 deaths, = 24.7 per cent. mortality. Birmingham Hospital for Women, 632 cases, with 49 deaths, = 7.7 per cent. mortality.

One point as to the value of the spray, quoting from Keith's report of cases treated in the Royal Infirmary, Edinburgh:

Carbolic Acid Spray Cases.

Ovariotomy, 21 cases; 18 cured, 3 died.

Hysterectomy for fibroid, 2 cases; 2 cured, 0 died.

Battey's operation, 1 case; 0 cured, 1 died.

Twenty-four cases, with four deaths, = 16.66 per cent.

Boro-Glyceride Spray Cases.

Double ovariotomy with hysterectomy, 1 case; died.

Hysterectomy for fibroid, 1 case; recovered. Result with boro-glyceride spray, 2 cases, with 1 death.

No Spray.

Ovariotomy, 47 cases; 46 cured, 1 died.

Hysterectomy for fibroid, 7 cases; 7 cured, 0 died.

Battey's operation for fibroid, 1 case; 1 cured, 0 died.

Interstitial pregnancy, 1 case; 1 cured, 0 died.

Total, fifty-six cases, with one death.

Mr. Keith says, "No cases of serous cysts of the broad ligament were operated on. These all were treated by tapping, and none of them have returned." One such case that Dr. Price saw died a few days later. Of Dr. Keith's cases, one-half had no adhesions.

Dr. MONTGOMERY expressed pleasure at hearing Dr. Goodell's details and success, and considered his success gratifying, especially after tapping. A patient came to him one month after tapping. She had a high pulse, septicæmia, large adhesions to viscera, etc., putrid clots in the tumor, and died on the fifth day with a temperature of 105°. He does not approve of tapping broad-ligament cysts. One patient with such a tumor was tapped seven times. He afterwards removed the tumor, and did not have a single vessel to tie. In this case the peritoneum had been pushed up by the tumor, and was not opened until late in the operation.

Dr. GOODELL made a few remarks on the subject of statistics. Dr. Keith's have improved not because he has given up the spray, but because he has grown to his work. Dr. Goodell will give up the spray because it is an intolerable nuisance. As to the question of the malignancy of ovarian tumors, it has been said that "all ovarian tumors are malignant, and should be so treated." This is too sweeping; but the tumor should in all cases be removed as soon as possible, as soon as it is discovered.

Dr. R. P. HARRIS desired Dr. Parish to report the present condition of the patient from whom he had removed the ovarian tumor exhibited by him before the Society at its meeting on March 4, 1886, the day after the operation.

Dr. PARISH requested Dr. Harris, who had seen her much more recently than he had, to report her condition.

Dr. HARRIS stated that notwithstanding the fact that the tumor was largely solid, that it had grown rapidly, that the solid portion had an appearance of malignancy, and that there was a small morbid growth projecting upward from the fundus uteri, the lady was to all appearance a well woman. He saw her on December 26, when she claimed to have perfectly recovered her health and strength after a very prolonged convalescence. Her appearance and activity certainly indicated that her statement was correct. The uterine nodule must have been a fibroid, as had it been cancerous it must have materially developed in nine months. The future of this case will be of much interest.

(To be continued.)

PHILADELPHIA NEUROLOGICAL SOCIETY.

MEETING OF DECEMBER 27, 1886.

(Continued from page 296.)

A PAPER by Dr. F. X. DERCUM was next read, on

EPILEPTIC BRAINS.

(See page 304.)

DISCUSSION.

Dr. CHARLES K. MILLS: The specimens presented by Dr. Dercum have great value. It is in part at least by studies of this kind that we will eventually discover the basis of epilepsy and of some forms of insanity. All genuine investigations are practical, and in studies of this kind an outcome of good is evident, even from the practical as it is ordinarily regarded. Of the many classifications of insanity which have been attempted, that of Dr. H. M. Bannister, of Illinois, is to my mind the best, although open to some criticism. His classification is into first primary and next secondary insanities. Under primary insanities he ranges (1) teratological forms, dependent on original structural defects; (2) pathological forms, dependent on alterations due to disease; (3) mixed forms, generally pathological, but in part probably due to original structural defect. Under his first head of teratological forms he embraces cases of idiocy, imbecility, and what he chooses to term pseudo-paranoia. The point is that these are cases which can only be demonstrated through morphological or teratological conditions such as are present in the brains exhibited this evening. By studies of the kind made by Dr. Dercum we are helped towards a fundamental understanding of insanity, and therefore towards better systems of classification. In regard to some of the apparent hypertrophies present, the idea suggests itself that these may be due not so much to overgrowth as to lessened resistance of the bony envelope.

These studies are but the beginning of a great work. Valuable as this work is, it is but the pioneer work,—the study of abnormal cerebral surfaces. Before long these investigations will be carried below the surface, and will be histological as well as researches in gross anatomy.

Dr. I. MADISON TAYLOR: It is well known that in most of the subjects of the convulsive disorders of childhood there are found distinct evidences of rickets. Some writers have said that at least thirty per cent. of children with convulsive disorders present marked rachitic changes. Gowers states that in fully ten per cent. of all epilepsies rickets is a predisposing cause. This would seem to bear upon the subject of brain-changes due to faulty bone-growth.

Dr. J. HENDRIE LLOYD: I would ask Dr. Dercum, with reference to the onset of the epileptic symptoms in these cases, and more particularly as to the form of insanity which they presented, whether in all of the cases the disease was due to hereditary abnormality of development, or whether some presented acquired forms of insanity.

Dr. FRANCIS X. DERCUM: In many of these cases the history was obscure. Ten of the twelve cases were ordinary epileptic dements. In one case, that which presented the large cuneus, the patient was an epileptic imbecile, and had been so from early childhood. The other specimen is from an epileptic maniac. He presented attacks of epileptic fury. It seems to me that our notions of epilepsy are not altered by the different forms under which the disease presents itself: whether it manifests itself by an intellectual or emotional explosion, as in mania, or by a motor explosion, as in the convulsions of ordinary epilepsy. We may find, as Gowers points out, cases where there is, instead of an explosion, a sudden arrest of all the processes. Again, the condition might show itself simply by the epileptic aura. There might be a sensory explosion without any motor disturbance. We should not limit our idea of epilepsy simply to the motor disturbance. The point in epilepsy seems to be that the normal interchange of function between the different parts is not kept up, this being rendered impossible by the abnormal construction of the parts. They are out of proportion to each other.

Dr. CHARLES A. OLIVER read a paper giving

AN ANALYSIS OF THE OCULAR SYMPTOMS OBTAINABLE IN EPILEPSY IN THE MALE ADULT.

(See page 306.)

DISCUSSION.

Dr. LOUIS J. LAUTENBACH: The subject which has been discussed by Dr. Oliver has been for the past three or four years worked

upon by myself, both among male and female subjects, and among those not insane as well as among the insane. The cases have been both from hospital and private practice. Within the past week I have seen three patients with the ordinary epileptic symptoms. One of these had the typical eye-ground which Dr. Oliver mentions. This was a case of idiopathic epilepsy. In another case, supposed to be one of syphilitic epilepsy, the eye-ground was different. In the third case there was still another picture, and in this instance the convulsions were due to the presence of a brain-tumor.

It is an interesting as well as instructive fact that there is a close resemblance between the eye-ground in a case of imbecility and that in a case of epilepsy: so far as I know, there is no essential point in which they differ.

There is one point which Dr. Oliver has not mentioned that I have noted, and that is that in perhaps one-third of the cases examined, and especially in those seen in insane hospitals, the macular region presents a red granular appearance, and, in addition thereto, the macula itself was of a dull red color. I have not observed the darkness of the color of the blood to which reference has been made.

Gowers states, as the result of the examination of a thousand cases of epilepsy, that there is only one condition that appears to be somewhat frequent in these cases, and that is that the arteries and veins appear to be about equal in size. It is strange that a careful observer like Gowers has not noted the thickening of the fibrous tissue of the retina which has been described by Dr. Oliver, and which is usually the first thing that is observed upon examining the fundus. In examining these cases I was struck with the frequency of high grades of hypermetropia, the proportion being greater than is observed among healthy individuals.

There is another point of some interest, and that is that in long-standing epilepsy, where the attacks have been very frequent or severe, it frequently happens that the nerve presents very marked signs of degeneration, the atrophy being decidedly advanced, the direct form of vision being well preserved.

Dr. Francis X. Dercum: The use of the ophthalmoscope in epilepsy for diagnostic purposes I regard as of comparatively slight value, for the diagnosis is usually made with ease from the history. The chief value is the light which it throws upon the pathology. Other things being equal, there is a certain correspondence between the condition of nutrition in the retina and the nutrition of the cerebral tissues. There is a certain amount of agreement between the ophthalmoscopic appearances and the microscopic appearances of the brain-tissue. In one case of epilepsy in which Dr. Oliver examined the eye-ground, the patient subsequently died, and section of the brain showed changes similar to those found in the eye. There was a similar tortuosity of the vessels, a similar infiltration of the sheath of the vessels, and a general increase in the neuroglia.

Dr. Charles A. Oliver: I am not now prepared to give any data in reference to the similarity of the eye-grounds of the imbecile and the epileptic, although I am pursuing investigations among the imbeciles at the Norristown Hospital for the Insane. Also, as I have before noted, I have carefully avoided any endeavor to make any differential diagnosis as to the causation of the convulsions. Inequality of pupil independent of local adhesion can be readily understood when differences of vision and accommodative action dependent upon refractive error, etc., which are so often seen in the two eyes of the same subject, are considered. These were carefully studied and purposely excluded, merely giving the pupillary reactions, sizes, and shapes, *as a rule*, although in a number of instances, especially where there was unequal contraction of the visual fields, I found some curious errors in the innervation arcs of the irides. In reference to the occurrence of high degrees of hypermetropia (varying from four to five dioptrics), I must say that I have not found this to be the case, at least in those subjects that were at my disposal. The fact that the amount of grayness of the disk in some instances seems to bear no absolute relation to the amount of nerve-degeneration —as was curiously shown in a series of observations made some years ago upon young, seemingly healthy males, in which I found that those nerves which were apparently extremely gray had excellent quantitative color-perception, while some of the nerves which appeared of good healthy tint had not as good (none of these cases making a single mistake in Holmgrem's loose-wool selection, and all having perfect acuity for form)—is curious, yet it must be admitted that the amount of vision and color-perception seen with degeneration of nerve-tissue is dependent upon the squeezing or atrophy to which the nerve is subjected. Those of Gowers's observations which were made during or immediately after a convulsive attack were extremely difficult to manage, although limited to cases in which the seizure began locally. His assertion that during the intervals of the fits there are no abnormal ophthalmoscopic appearances can, I think, hardly be borne out. In framing the conclusions which I have presented, I have grouped all the symptoms, both subjective and objective, into an average case, hoping thereby to obtain a somewhat typical picture. The peculiarities of the eye-ground seen in the cases I have studied—those of long-standing attacks of frequent occurrence—are most probably explained by the presumption that every convulsive discharge leaves an additional pathological condition, by which the

objective appearances of a low and chronic form of retinitis and perivasculitis, associated with dirty red-gray degeneration of the optic nerve, are at last established as the visible living results of a similar process which has been taking place within the intracranial substance, and which may be readily seen post mortem by careful microscopic examination.

Dr. GRANVILLE FAUGHT exhibited, by invitation, a new milliampère-metre, made by Waite & Bartlett; also a pole-changing electrode-handle.

Dr. CHARLES K. MILLS exhibited Rudisch's new portable galvanic battery.

Adjourned.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting of the Academy was held January 20, 1887, the President, A. JACOBI, M.D., in the chair.

THE VALUE OF QUININE AS AN ANTIPYRETIC IN PNEUMONIA.

Dr. JOHN H. RIPLEY read a paper on this subject, it being based principally on the histories of forty-eight cases treated in the St. Francis Hospital. This number included only those cases in which the experiment was carried out under careful observation of the patient's symptoms and the effects of the drug; in many other cases, with less complete histories, the results from the use of quinine were similar. The drug was given only in cases in which the temperature had reached at least 103° F. The quinine was given usually by the mouth and in solution, sometimes hypodermatically, sometimes by the rectum. No experiment lasted less than four hours, and usually not less than six to twelve hours. In the earlier cases the temperature was taken every fifteen minutes, later half-hourly or hourly, and always by the rectum. The effect of the drug on the pulse and respiration was noted in about two-thirds of the cases. When but a single dose was given during the day, it was usually in the morning; but all parts of the day were represented. Nearly all the patients were adult males, from nineteen to forty-five years. In twenty experiments a single dose of twenty grains of the sulphate of quinine in solution by the mouth was given: in five, thirty grains; in three, thirty grains were given in five-grain doses every two hours; in two cases thirty-five grains were given in the latter way; in eight cases forty grains were given at a single dose by the mouth; in three, twenty grains hypodermatically; in three, fifteen grains hypodermatically; in one, eight grains hypodermatically. The reduction in temperature which took place was always of short duration. There was no uniform time as to when the temperature began to fall, nor as to the duration of the fall: in a large number of cases there was a slight lowering of the temperature within fifteen minutes; in others it began to fall within half an hour to three hours. The time from the beginning of the fall to the permanent rise was from two to ten hours. But the temperature, even when taken every fifteen minutes, was found to vary constantly. The effect on the pulse and respiration was neither constant nor uniform, and the pulse and respiration did not constitute a sure guide as to the effect upon the temperature. Of the six cases in which the temperature was reduced more than two degrees, in four there was malarial poisoning. Giving reasons for excluding these cases excepting one, he said that the greatest reduction in temperature obtained was only one degree and a fraction, except in a single instance. Practically, as far as we could judge from these experiments, the most that we could expect from the administration of from twenty to forty grains of quinine administered daily in the active stage of lobar pneumonia was a reduction of the temperature between one and two degrees Fahrenheit in about half the cases, while in the other half the reduction would amount to less than one degree. When he added that the lowest point reached did not continue approximately more than two hours, the results appeared even less striking. It was not improbable also that in a number of cases the effect of the drug in reducing the temperature was only apparent, for there were recessions of the fever in pneumonia without medical treatment.

The conclusion that quinine was a feeble antipyretic in pneumonia was arrived at by his experiments. But, besides being only a feeble antipyretic, there were other objections to its use. In even moderate doses it produced anorexia and nausea, and in large doses it not unfrequently excited retching and vomiting, prolonged intolerance of food and stimulants, marked cardiac weakness lasting several hours, sometimes associated with dicrotic pulse. Profuse, often cold, perspiration was another effect; epistaxis occurred in about twelve per cent. of the cases; profound nervous depression, somnolence, delirium, muscular twitching and trembling, dilated pupils, in two instances opisthotonos, were among the effects upon the nervous system. In three cases in which a thorough examination of the urine was made, the albumen was found increased in quantity after taking quinine, and in one there appeared renal casts which had not been present before. In his opinion, these injurious effects of quinine more than counterbalanced any good arising from the slight temporary reduction in the fever which it produced. He had not been able to find evidence that it ever shortened the course of the disease or lessened the mortality.

Dr. RIPLEY thought that too much importance had been attached of late to the reduction of the temperature in disease, especially when of moderate degree. In typhus and

typhoid fevers, for instance, of which we had had during the past few years quite a number of cases in the hospitals, the mortality had been markedly less after abandoning the former heroic measures for reducing the temperature. Why should it be necessary in a case of ordinary pneumonia, running a short course, to ply the patient with antipyretics? That quinine had any influence in arresting cell-migration might well be doubted. If an antipyretic were indicated in pneumonia, antipyrine and even salicylic acid were more powerful and less dangerous than was quinine.

Dr. M. Putnam Jacobi thought, from experience in the treatment of pneumonia in dispensary children, that quinine could not be relied upon as an antipyretic; that antipyrine was more suitable.

Dr. J. Lewis Smith had found quinine to be a very good emetic in children, and he thought it probable it may have sometimes been vomited when the physician was not informed of the fact. He would give it only in small doses and as a tonic in pneumonia.

Dr. Fruitnight, Dr. Castle, Dr. Billington, and Dr. Holt had not found quinine a useful antipyretic in pneumonia; other measures were preferable.

The President seldom gave quinine for its antipyretic effects in pneumonia at the present time, as antipyrine, for instance, was more efficient. But some years ago he employed it and had obtained benefit from its use. It was important that it should not be given during the height of the fever, as it would not then be absorbed and would injure the digestion; if given hypodermatically, the carbamide of quinine was the best form to administer. At the time he referred to he was in the habit of giving from six to ten grains during the day to a child, and he got the name of overdosing; now, however, many physicians gave much larger doses, but without getting the unpleasant appellation which had stayed with him, notwithstanding he gave no larger doses than formerly, now looked upon as moderate.

NEW YORK PATHOLOGICAL SOCIETY.

THE annual meeting was held January 12, 1887, Dr. T. Mitchell Prudden, the Vice-President, in the chair.

THE "BRONCHIAL TREE."

Dr. W. P. Northrup presented the lung of a child 3 years of age, dead of broncho-pneumonia, the interest in the specimen being that, by a favorable cut with the knife, the so-called bronchial tree was very beautifully shown.

SYPHILITIC LESIONS OF THE LUNGS.

Dr. W. H. Porter presented specimens similar to those which he had presented at a late meeting of the Society, illustrating the syphilitic lung. The bacillus tuberculosis was not found, after the most careful search.

THE LESIONS OF THE DIFFERENT STAGES OF BRONCHO-PNEUMONIA.

Dr. L. E. Holt presented the specimen, which was chiefly of interest as showing the lesions of broncho-pneumonia of only two or three days' duration at one part of the lung, of about three weeks' duration at another part, and of eight weeks' duration at another part. The child was taken sick with the usual symptoms of broncho-pneumonia eight weeks before: there was a relapse about five weeks later, and again before death.

TYPHOID FEVER SIMULATING CEREBRO-SPINAL MENINGITIS.

Dr. R. W. Amidon presented the intestine of a woman aged 30 years, showing well-marked lesions of typhoid fever; many of the ulcers in the lower part of the ileum having healed, but some in the large intestine still in a sloughing condition, as was the one from which fatal hemorrhage had taken place the day before. The patient was taken ill November 19, 1886, with pain in the back of the head and neck, and later she had chills. The pain in the back of the head increased, and a doctor was called. The temperature was 103.8°, higher in the morning by one or two degrees than in the afternoon. The morning temperature throughout the sickness was nearly uniformly higher than the afternoon temperature, and in other regards the temperature-course was very irregular. The cerebro-spinal symptoms were marked throughout the attack. Dr. Amidon saw the patient in consultation once. There was no special tenderness over the abdomen, no ileo-cæcal gurgling nor eruption. Later there was a scarlatina-like eruption in patches all over the body. The temperature became nearly normal on two or three occasions, but again rose from impropriety of diet, and a few days before death it was the temperature of pyæmic or septic poisoning. The diagnosis had been in favor of cerebro-spinal meningitis. But it was now changed to typhoid fever, as this seemed best to account for the septic poisoning. The patient was doing well when suddenly intestinal hemorrhage took place and resulted fatally. Dr. Amidon said the text-books did not mention cerebro-spinal meningitis in speaking of differential diagnosis in connection with typhoid fever. He had found only one case in literature, after brief search, in which septicæmia followed typhoid fever. The spinal cord in the case which he related was normal; the cranial cavity was not opened.

At the executive session Dr. T. Mitchell Prudden was elected President, and Dr. W. P. Northrup Vice-President.

REVIEWS AND BOOK NOTICES.

DISEASES OF TROPICAL CLIMATES. Lectures delivered at the Army Medical School. By WILLIAM CAMPBELL MACLEAN, M.D., C.B., Surgeon-General, late of H.M. Indian Army, etc. London and New York, Macmillan & Co., 1886. Post 8vo, pp. 337, cloth.

The lectures delivered at Netley by Professor MacLean, whose long medical experience in hot climates enables him to speak with authority upon the subject, will be read with pleasure by the profession. The various manifestations of malaria, enteric fever, febricula, relapsing fever, dengue, yellow fever, insolation, bowel disorders, cholera, diseases of the liver, beriberi, and Guinea worm are considered consecutively, the lectures terminating with a farewell address. The statistics, results of clinical and post-mortem observations, discussion of questions of pathology and therapeutics, and observations upon the climate of India, are of more than transient importance. His remarks upon the treatment of cholera acquire special interest from the fact that personal experience as a sufferer dictated the advice as to treatment. Opium early or not at all, an abundance of iced water, even though vomiting seems increased by it, and the entire abolition of stimulants internally, the use of turpentine or chloroform externally to relieve cramps, or the inhalation of a few whiffs of the latter, and rest in a horizontal position, are the main points to be observed in the treatment. Immediately upon the appearance of the first signs of reaction assiduous nutrition should begin, commencing with arrow-root made with water, with beef-tea enemata, and measures directed towards the restoration of the functions of the kidneys. Calomel in large doses is considered objectionable, both on account of the idiosyncrasy of some patients to mercury and because he had seen it cause ulceration of the stomach. The extravagant recommendation of some remedies as specifics seem, in the mind of the author, based upon the fact that "remedies used towards the end of an epidemic often obtain an undeserved reputation,"—a remark which applies in other diseases as well as cholera.

THE SCIENCE AND PRACTICE OF SURGERY. With One Thousand and Ninety Illustrations on Wood, mostly New and Original. By FREDERICK JAMES GANT, F.R.C.S., etc. Third Edition. Revised and much enlarged throughout. In Two Volumes. Pp. 1089, 1183.

The importance of clinical study of life, both under healthy and morbid conditions, is maintained by the author of this handsomely-printed system of surgery, the motive being to keep before the reader the teachings of anatomy and physiology in essential connection with the rational practice of surgery. It is upon the assumption of a deficiency in this regard in others that the author of this work proceeds. The present edition has been carefully revised and a large number of illustrations added. As in former editions, special sections have been prepared or revised by well-known authorities upon their individual subjects. The chapters on Diseases of the Eye, the Ear, and the Teeth have been undertaken respectively by Mr. Henry Power, Senior Ophthalmic Surgeon to St. Bartholomew's Hospital; Mr. W. Laidlaw Purves, Aural Surgeon to Guy's Hospital; and Mr. Charles S. Tomes, F.R.S., Examiner in Dental Surgery to the Royal College of Surgeons. "Diseases of the Throat and Larynx" is contributed by Morell Mackenzie; "Deformities," by William Adams; "Diseases of the Skin," by Malcolm A. Morris; "Diseases of the Female Genital Organs" has been revised with the aid of Dr. Robert Barnes, and "Cleft Palate" by Mr. William Rose. A description of the Sphygmograph and its application was contributed by the late Dr. Mahomed.

The care which has been exercised in bringing this edition to its present position constitutes it a fair expression of modern British surgery. It probably fairly represents the practice of surgery in England, and is consistent in its failure to understand the principles of asepticism in the dressing of wounds, and the revolution which they have achieved in practical surgery. On page 437 the principle of Listerism is said to consist in "the exclusion of air as the infecting agent from the wound," and "the interposition of some positively disinfecting or antiseptic dressing." This view leads to various expedients to keep air from the wound, such as keeping it covered with water or oil, or by the use of the spray, all of which will prove inefficient if the fundamental precaution is neglected, which is the key-note of modern surgery, "make and keep the wound aseptic." Where this is accomplished, antiseptic surgery has been successfully applied; where it fails to be accomplished, and bacterial infection occurs, the application has been faulty.

If the remainder of the work were written up to the standard of Watson Cheyne's article, it would better represent the surgical pathology of to-day. The chapters on inflammation, suppuration, tuberculosis, and hydrophobia need to be revised from this point of view. The propriety of devoting a chapter to rheumatism and gout, or to hysteria or delirium tremens, in a system of surgery, is questionable. Apart from these criticisms, which we feel obliged to make, we find the subject-matter interesting, the illustrations good, and the treatment that which will receive the approval of clinical surgeons generally.

NEW REMEDIES AND CLINICAL NOTES.

To Ascertain if Gangrene is likely to follow Severe Injury of a Limb, Dr. W. Scott Lang advises elevating the injured member in order to render it temporarily anæmic; next applying an elastic bandage or tourniquet for a minute; then lowering the limb and removing the tourniquet; when, "if sufficient circulation remains, the part beyond the seat of injury will blush rosy-red, and will show in an unmistakable manner the condition of the blood-vessels." This expedient was adopted by the writer in a bad case of railway-crush of both bones of the leg, where the limb was almost dangling and apparently hopeless. Under antiseptic treatment (after removal of fragments of bone and securing bleeding points), the boy made an excellent recovery with a useful limb.—*Edinburgh Medical Journal*, January, 1887.

Aconite in the Treatment of Pneumonia.—The treatment of pneumonia by tincture of aconite is not new, but its endorsement by Surgeon J. D. T. Reckett, of the Army Medical Staff (*Indian Medical Gazette*, October, 1886), is so unequivocal that it deserves attention.

For six years nearly every case of pneumonia which has come into his hands has been treated with aconite, and in this period he has had only one case which ended fatally. In adult men of florid complexion, high temperature, rapid and full pulse, and usually dyspnœa and pain, he gives five minims (B. P.)—equivalent to gtt. j–ij, U. S. P.—every two hours with half an ounce of water, until the urgent symptoms are relieved; subsequently wine of ipecac and solution of acetate of ammonium are substituted. Hot poultices of flaxseed are applied, and low diet given. The disease, thus treated, rarely passes into the second stage of red hepatization.

Anisic Acid, a New Antiseptic.—By oxidation of oil of anise, anisic acid is obtained, which is isomeric with methyl-salicylic acid and has germicidal properties. The anisate of soda does not disagree with the stomach, reduces temperature, and increases intravascular pressure. It may be used in surgery as an antiseptic, or in the treatment of acute articular rheumatism as a succedaneum of salicylic acid.—*Rev. de Thér. Méd.-Chir.*

MISCELLANY.

"Physical Culture in Amherst College," by Dr. Nathan Allen, of Lowell, Massachusetts, was the title of a valuable paper read at the Academy of Medicine upon a subject which is now coming quite prominently before the profession and public. Amherst introduced physical culture twenty-six years ago, and Dr. Allen has been chairman of the committee on that subject of the Board of Trustees during all that time. The paper spoke with authority. The principle determined upon at the start and carried on during the whole time has been—

1st. The putting of the department under the care of a competent physician, who was a member of the faculty and on equal standing with the other professors. This person also gave lectures on hygiene and human physiology.

2d. A personal investigation, accompanied by measurements, to see the departure from the normal standard of the individual, and also if there was a physical condition which might prevent his taking exercise in any form.

3d. A compulsory attendance upon a certain amount of light gymnastics upon the part of all students whose physical conditions will permit it.

4th. Special exercise is suggested to all who do not come within the limits of the normal standard, having a tendency to bring them up to the standard.

5th. A full and free opportunity for consultation between student and professor on health subjects: indeed, the excuse from college duties on account of sickness is a matter for investigation on the part of the professor.

As a consequence of this, the results have been in every way satisfactory. There are fewer days lost from sickness, fewer students break down during their college course, while the strength and vigor of the men have increased from year to year.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 16, 1887, TO JANUARY 29, 1887.

Major W. H. Forwood, Surgeon.—Ordered for duty at Fort Meade, Dakota Territory. S. O. 5, Department of Dakota, January 14, 1887.

Major John Brooke, Surgeon.—Ordered for duty as post-surgeon at Fort Monroe, Virginia. S. O. 10, Division of the Atlantic, January 14, 1887.

Major W. H. Gardner, Surgeon.—Ordered for duty as post-surgeon at Fort McHenry, Maryland. S. O. 10, Division of the Atlantic, January 14, 1887.

Major B. F. Pope, Surgeon.—Ordered for duty at Fort Clark, Texas. S. O. 15, A. G. O., January 19, 1887.

First-Lieutenant Edward R. Morris, Assistant-Surgeon.—Granted leave of absence for one month, to take effect about March 10, 1887, with permission to apply for an extension of twenty days. S. O. 6, Division of the Pacific, January 19, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U.S. MARINE HOSPITAL SERVICE FOR THE SIX WEEKS ENDED JANUARY 29, 1887.

Wyman, Walter, Surgeon.—Granted leave of absence for three days, January 14, 1887.

Wheeler, W. A., Passed Assistant-Surgeon.—To proceed to Erie, Pennsylvania, as inspector, January 12, 1887.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON TYPHOID FEVER COMPLICATED WITH ULCERATIVE ENDOCARDITIS AND CATARRHAL PNEUMONIA.

Delivered at the Hospital of the University of Pennsylvania, November 27, and December 4 and 11, 1886,

BY WILLIAM PEPPER, M.D., LL.D.,

Provost of, and Professor of the Theory and Practice of Medicine and of Clinical Medicine in, the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M.D.

GENTLEMEN,—This young man came to my office four days ago, evidently very ill. I at once sent him to the hospital. He was admitted here the same day, November 23, 1886. He is 22 years of age, and a German by birth. He has had the ordinary diseases of childhood, but has never had rheumatism nor any venereal disease. He enjoyed good health until the winter of 1881–82, when he had what seems to have been, from his account of it, some form of kidney disorder. Following this he had a spell of catarrhal jaundice lasting three or four weeks. Since that time he has never been entirely well. The appetite, as a rule, is poor; thirst excessive; the urine scanty. He has been engaged as a nurse in this and other hospitals. He has also acted as a porter. In June, 1885, he was in this hospital suffering with a catarrhal affection of the intestinal mucous membrane, which lasted three days. In May of the present year (1886) he was again admitted into this hospital, and it was then evident that he had chronic catarrhal nephritis. The legs were swollen, there was pain on micturition, the urine was scanty, albuminous, and contained casts. He improved subsequently and left the hospital, although the legs and feet continued swollen. He went to work and continued for six weeks, when he was obliged to give up. He then had headache and dizziness, with œdema and scanty, high-colored urine. Four weeks ago he began to cough, but this was unaccompanied by expectoration. After the cough had continued a week, he vomited or coughed up a quantity of dark-colored matter, partly liquid and partly solid. This probably was altered blood, but whether it came from the stomach or from the lungs we cannot determine from his statements. Then he had another attack of catarrhal jaundice, and up to one week ago the skin was quite yellow. The cough still continued without expectoration. One week ago the bowels became loose, and he had as many as eight stools in one day. The patient stated that previous to admission he had not had fever; but this is improbable, for when he came here the temperature was 104°.

When admitted, he was dull and drowsy. The breath had a sweetish odor, the pulse was 108, and the respirations 30 per minute, and, as I have stated, the temperature was 104°. The urine was passed with straining, and the act was attended by some pain in the penis. It was high-colored, and the specific gravity was 1026. There was a trace of albumen and an increased amount of indican, but no sugar. The microscope showed a large quantity of phosphates and some swollen granular epithelium stained yellow, and also a few bodies looking like granular tube-casts. The quantity of urine passed was forty ounces in the twenty-four hours. There was some abdominal soreness, especially in the right iliac fossa, and there was some gurgling in that situation. The man complained of headache and loss of appetite. There was cough, but no expectoration. The area of cardiac dulness was not materially increased. At the apex a distinct systolic murmur was heard.

He was at once put to bed and a jacket-poultice applied. Aconite was given in drop-doses every hour, and small doses of opium to quiet the bowels were administered. The evening of admission the temperature went up to 104.2°, and eight grains of antifebrin were given, with the effect of reducing the temperature to 100.4°. The following day, examination of the chest showed some dulness at the bases of both lungs, probably due to hypostatic congestion. The tongue was dry and coated. The drowsiness continued. There was slight epistaxis. The murmur heard at the apex was more distinct and rougher. In the evening the temperature again went up to 104.2°. Sponging of the surface was then resorted to, and the temperature came down to 101.2°. The following morning it was 101°. Expecto-

ration then began, and since then he has been coughing up dark-colored mucus stained with altered blood and presenting a small amount of red blood. Over the base of the lung there was still impairment of resonance. There was deficient expansion of the upper part of the chest. Here and there through the lungs are detected indications of consolidation. For instance, at the upper part of the right lung there is increased fremitus, the resonance is slightly impaired, and the breath-sounds are harsh and bronchial, with prolonged expiration. Posteriorly, over the corresponding area, the same signs are found. Here and there through the lungs fine râles are heard. Last night the nose bled quite freely. The temperature was 103°. To-day the temperature is 102.5°. There is no eruption.

The condition of this patient is evidently a very grave one, and the diagnosis is attended with much obscurity. The history is bad. The man has had a good deal of sickness, for the most part of a catarrhal type, as catarrhal jaundice, gastro-intestinal catarrh, pulmonary catarrh, and, what is most serious, catarrhal nephritis. From the history of the case, I fear that we must assume that there is some chronic Bright's disease. The condition of the urine would not indicate that the kidneys are very seriously affected. It contains only a small quantity of albumen. Forty ounces of liquid are secreted in the twenty-four hours. This is high-colored, and throws down a heavy deposit of urates and phosphates. The man is just recovering from another attack of catarrhal jaundice, but we find no distinct traces of bile pigment in the urine. Repeated examinations of the urine have failed to reveal distinct tube-casts, simply showing bodies looking like broken fragments of tube-casts. The examination of the urine does not give very conclusive evidences as to the existence of serious chronic Bright's disease.

Finding a person in the profound comatose condition which this man presents, it would be easy to say that he is in a condition of uræmic coma from chronic Bright's disease. Such a view, however, cannot be sustained, although we cannot say that there is not some uræmia. The idea of uræmia cannot be maintained, in the first place, on account of the favorable condition of the urine. If the kidneys had advanced to such a state of disintegration that the condition was due to arrest of the function of the kidneys, we should find in the urine more positive evidences of disease. In the second place, ever since the patient came under observation there has been very high temperature. There is nothing in the ordinary condition of uræmia to explain this high temperature. In uræmia there may be some local congestion or irritation which will cause a slight elevation of temperature, but not to 104° and obstinately recurring. We must assume some additional lesion to explain the high temperature, and this additional element probably goes far to explain the present typhoid condition.

Our attention is at once directed to two or three things. In the first place, has not this man typhoid fever? If he has not typhoid fever, might he not have catarrhal pneumonia? Lastly, is it possible that we have here a case of ulcerative endocarditis of the typhoid form? These are the questions which suggest themselves in connection with this serious case.

Has this man typhoid fever? There is much in support of such a view. He has been exposed in many ways; his health was broken down, and he was in a condition to contract such a disease. We have a febrile process of irregular type, about as we should have it in the second week of typhoid fever. The man had lost appetite and had been feeling very ill for a week before he came to the hospital, when we found the temperature corresponding to what is usually found in the middle of the second week of typhoid fever. Then he has had cough. There has been congestion of the bases of the lungs; there has been diarrhœa amounting to several stools in the day. The diarrhœa has subsided under rest, proper diet, and the use of opium. There has been epistaxis. Abdominal pain and tenderness in the right iliac fossa, with gurgling, has also been present. The patient has been dull and drowsy, and irritable when disturbed. All these symptoms are among those of typhoid fever. It is to be observed, however, that the characteristic symptom of typhoid fever, the eruption, is wanting. But before we decide against typhoid fever we must be prepared to say, if it be not typhoid fever, what it is. In any case where there is present a febrile process, you first seek for a local cause to explain the high

temperature; failing in this, we must assume that the fever is essential,—that is, a specific fever. We shall leave for a time the evidences which point to typhoid fever, simply saying that they are suggestive rather than demonstrative.

Is there evidence of any local inflammatory condition which would explain these symptoms? Is there any catarrhal pneumonia? This is a disease which is often overlooked. Its physical signs are sometimes quite vague and indefinite as contrasted with the sharply-cut and easily-recognized signs of croupous pneumonia. The patches of catarrhal pneumonia may be small; they may be deeply seated and widely separated, and you do not find marked percussion-dulness and strongly increased fremitus and resonance. Catarrhal pneumonia is a disease which comes on in low states of the system. It may come on in cases where there has been catarrh of the upper air-passages, which extends downward until the alveolar structure is involved. In catarrhal pneumonia it is not uncommon to have the temperature as high as it has been in this case. The cough is at first dry and hard. Then expectoration begins, the sputa usually consisting of mucus, and gradually becomes purulent in character. As a rule, it is not rusty-colored or blood-stained, yet in low grades of catarrhal pneumonia, where the crasis of the blood is much impaired, or when the disease attacks old people or those much debilitated, there is a great deal of hypostatic congestion, and as a result there may be in catarrhal pneumonia expectoration of blood-stained mucus and of disintegrated blood, and even of a little fresh blood. The expectoration present in this case is therefore not inconsistent with the view that the man has catarrhal pneumonia. Again, catarrhal pneumonia, coming on in a low state of the system, is very apt to pass into a typhoid form. This is particularly apt to occur where the disease affects a person with damaged kidneys. Catarrhal pneumonia is not a rare complication of Bright's disease, and, as I have just stated, it is under these circumstances extremely apt to run into the typhoid form and induce uræmic symptoms. There is therefore much in favor of the view that this man's condition is due to scattered centres of catarrhal pneumonia associated with Bright's disease. As between the adoption of the view that the patient has true typhoid fever or simply the typhoid state with centres of catarrhal pneumonia, I should, in the absence of the characteristic eruption, incline to the adoption of the latter view, and should say that, on the whole, the evidence is against true characteristic typhoid fever. Associated with catarrhal pneumonia there is not rarely a catarrhal irritation of the intestinal mucous membrane. We know that this patient has presented this condition.

Even if we consider the evidence favorable to this view of the case, there is one important point that this condition would not explain, and that is the marked systolic murmur, for which we must find an explanation. This man has not had rheumatism. There is no history of cardiac disease, and there is no record that such condition was detected during his previous stay in the hospital. Neither the presence of catarrhal pneumonia nor of typhoid fever would account for this murmur. The cardiac change is not that which we find in renal disease. The heart is not hypertrophied. If the valvular lesion which gives rise to this murmur had existed for any length of time, we should have expected to find hypertrophy. There is therefore reason to think that this is a recent condition. Is this a blood-murmur, or is it an organic murmur due to alteration in the valve? This murmur is heard at the apex, while a blood-murmur is, as a rule, heard at the base. A functional murmur is soft and not transmitted along the great vessels. This murmur is harsh, and has become rougher while the patient has been under observation, and it indicates—I will not say that it demonstrates—some organic change in the mitral leaflets.

If, then, we have a recent murmur, and it be organic in character, it indicates the presence of some acute endocardial process. We may have acute endocarditis of a simple type or of the ulcerative type. Simple endocarditis might occur as a complication of typhoid fever or of catarrhal pneumonia, or it might occur idiopathically. Whether it were a complication or an independent affection, it would not go far to explain the grave condition in which we find the patient. It would scarcely cause the high fever which is present; it would not provoke this dyscrasia of the blood, and it would not induce the profound typhoid condition which has developed within the past few

days. If there be any endocarditis present, it must be of the ulcerative variety.

Let us for a moment consider this rare affection. Ulcerative endocarditis is an ulcerative disintegration of a larger or a smaller area of the valves of the heart. As a rule, it attacks a heart which is the seat of organic disease. The health of the patient breaking down, violent inflammation attacks the diseased heart and runs into the ulcerative type. The affection may attack a heart previously healthy, provided the condition of the system is favorable to its development. Ulcerative endocarditis may run a very rapid course, and may end fatally in a very few days, or it may continue for weeks. Its symptoms are local and general. Its local symptoms are merely those of endocarditis. A murmur is found usually in the mitral area. The general symptoms are very grave. In the first place, we have fever of a very irregular, remittent type, sometimes associated with a distinct tendency to sweating. With this there is a rapidly-developing dyscrasia of the system, with anæmia, and often there is a slight icterode hue of the skin, which may amount to jaundice. There is excited action of the heart, with a rapid pulse. The spleen becomes enlarged, and there is evidence of pulmonary engorgement. This is due to the fact that in the course of ulcerative endocarditis fragments of the ulcerated tissue are detached and carried with the blood-current into various organs, forming infective emboli, around which secondary changes take place. These emboli may lodge in the lung, giving rise to scattered centres of embolic pneumonia, closely simulating the conditions found in catarrhal pneumonia.

If the evidence as to the presence of typhoid fever is not conclusive, and if we are satisfied that there are in the lungs scattered foci of disease, which, however, fail to explain the cardiac murmur, it is proper to consider whether or not all these symptoms might not be due to ulcerative endocarditis occurring in a broken-down system, where the poisoning of the blood from the endocardial disease, grafted on that due to the damaged kidneys, has developed this typhoid state. Even in those cases where the kidneys have previously been healthy, the occurrence of ulcerative endocarditis is nearly always accompanied by albuminuria and the presence of tube-casts. As you see, we are dealing with a very grave and obscure condition. The diagnosis is rendered obscure by the numerous signs of disease, and by the fact that we have not had the opportunity of observing the case from its very beginning.

Now as to the present condition. He appears to be sinking into a more and more profound stupor, out of which, however, he can be roused; but there could not be a more perfect demonstration of the typhoid state than is here seen. The temperature continues high. As you see, there are symmetrical conjunctival ecchymoses. These may possibly have resulted from the violence of the efforts in coughing. The pulse is rapid and weak. The belly is moderately distended. The cardiac murmur is stronger than when I first heard it.

I do not feel prepared at the present time to formulate a positive diagnosis. I have sketched for you the thoughts which have presented themselves in connection with the case. I should not be surprised if the case turned out to be one of ulcerative endocarditis, with scattered foci of disease in the lungs, spleen, and kidneys. In reference to the indications for treatment, there is no pain, the bowels are quiet, and the fever is readily controlled by sponging and by small doses of antifebrin. The most prominent indications for treatment are to control the heart's action and to relieve the pulmonary congestion-engorgement. In view of the profound depression of the system, I shall give turpentine in as full doses as possible. We shall order ten drops in emulsion every two hours. Antipyrine will be used should the fever become high. The heart's action will be controlled by aconite, and, if the heart becomes weaker, by digitalis. I shall report to you the further progress of the case.

(*Clinical lecture continued, December* 4, 1886.)

GENTLEMEN,—The patient whom you saw last week remains very much in the same condition as he was when before you. One or two points are, however, to be noted as indicative of the progress of the disease. In the first place, the profound typhoid condition has continued. In the second place, he has had stools, at times spontaneously and always liquid and of a yellowish color, like the stools of typhoid fever. There has been some epistaxis. The

bloody, grumous sputum has decreased in quantity and almost entirely ceased. The subconjunctival ecchymosis, which you will remember was symmetrical, involving the lower half of each globe, has increased in size. In addition, an eruption has appeared which at first very closely resembled the characteristic spots of typhoid fever. They were flat, of a reddish color, and scarcely elevated above the level of the skin, and were most marked over the abdomen and the lower part of the trunk. These spots soon became petechial in character. The urine still presents albumen, but no tube-casts. A careful examination of the blood for micrococci, made by Dr. Crozier Griffith, gave entirely negative results. The examination showed nothing unusual in the blood. The condition of the heart has remained about the same, the pulse ranging between 102 and 113 per minute.

The progress of the case during this week has been satisfactory, although it has not enabled us to decide positively with regard to the nature of the disease, but so far as it goes it tends to support the view of typhoid fever and not that of ulcerative endocarditis. When you saw him last week we supposed that the disease had reached the tenth day, and therefore the absence of eruption was against the supposition of typhoid fever; but since then an eruption has made its appearance, but it differs from the normal characteristic typhoid-fever eruption in that the spots soon became petechial.

I will rapidly run over the record of his condition since you last saw him.

"November 26. Free epistaxis.

"November 27. Expectoration consists almost entirely of pure blood. Subconjunctival hemorrhages distinct. A copious movement of the bowels occurred at 10 P.M.; the stool was of a yellow-ochre color, and very offensive.

"November 28. The nose again bled profusely. An eruption was noticed over the lower part of the chest. The belly is somewhat distended, and the spleen somewhat enlarged.

"November 29. The nose again bled. There were two stools, both of which contained liquid blood.

"November 30. Patient was dull and sleepy. The subconjunctival hemorrhages were more marked. The spots of eruption had increased in size, and some had become petechial. The systolic murmur was very distinct. There was no increased development of the signs of morbid action in the lungs.

"December 2. The condition of the patient was worse. He was quite drowsy. There were two movements of the bowels. He coughed a great deal. The murmur at the apex was still quite distinct.

"December 3. The patient was a little brighter; the temperature continued high, and the pulse 112. The spleen was still enlarged. There was some delirium."

What is the influence of the course of the case during the past week upon the diagnosis? I may say that the supposition of catarrhal pneumonia with the typhoid state may be excluded. While there are pneumonic patches throughout the lungs, they are evidently secondary. The renal complication seems to have little influence in causing the condition. It appears as though the man were able to throw off renal lesions with remarkable success. He had catarrhal nephritis. During the past two weeks a large amount of detritus has been thrown upon the kidneys, and they have been required to excrete a large quantity of irritating matter, and yet the urine has improved. Although the quantity is small, from twenty to twenty-four ounces in the twenty-four hours, the albumen has decreased, and no tube-casts are found. The diagnosis seems to be either typhoid fever, complicated with cardiac and renal disease and presenting certain peculiarities, or else ulcerative endocarditis, with a profound typhoid condition. The evidence of the past week seems to be in favor of typhoid fever with some very unusual features. The condition of the bowel, the appearance of the stools, the tendency to epistaxis, and the appearance of an eruption favor this view; yet it is excessively rare in typhoid fever to find the eruption assuming a petechial character. This would indicate, as do the subconjunctival hemorrhages, a degree of alteration of the crasis of the blood which is very extraordinary in typhoid fever.

The history of the past week renders the prognosis more favorable. The fact that he has lived a week in this condition indicates a degree of vitality which we did not expect. The treatment has consisted in the use of moderate amounts of stimulants, with quinine in full doses and turpentine.

[The patient was again brought before the class December 11, 1886, and the following remarks were made:]

GENTLEMEN,—I again bring before you the case which you have already seen. Although the course of the fever has been obstinately sustained, it has, on the whole, been downward. For the past four days there has been no temperature above 103°, and since November 26 it has not been above 104°. There has been a steady and gradual fall in the temperature; the temperature has gone as low as 100°, and even to normal. According to our calculation, the patient has reached the third week of the disease. Two weeks ago he was almost comatose, but it is impossible to look at the man without realizing that his condition has wonderfully improved. His intelligence is returning, and he is able to recognize those around him. He is still jaundiced, this being most marked in the conjunctivæ. The subconjunctival ecchymoses still continue. The pulse-rate still keeps up; it has fluctuated between 116 and 136. The respiration has improved decidedly: whereas two weeks ago it ranged between 38 and 40 per minute, it is now between 24 and 28. The grumous expectoration has ceased, and the cough is a great deal better; the signs of disease in the lungs have gradually diminished; the spleen is not so much enlarged as it was; the cardiac murmur is softer and less noticeable; the whole course of the case has been one of steady improvement from an apparently desperate condition.

The case, however, remains a very anomalous one. Its course would lead us to believe that it has been a case of typhoid fever complicated with extreme dyscrasia of the blood, leading to the formation of petechiæ instead of the ordinary eruption, complicated with catarrhal pneumonia, complicated with jaundice from breaking down of the crasis of the blood, complicated with a hemorrhagic tendency as shown in the ecchymoses and the expectoration of bloody sputa, complicated with damaged kidneys, and, lastly, complicated with a cardiac murmur from endocarditis. The theory of ulcerative endocarditis does not seem to be sustained. Two weeks ago I told you that the evidence favored that view. The improvement in the case is against the idea of ulcerative endocarditis, for, so far as we know, this is an incurable disease. The case, however, presents a great many peculiarities which are very rare in ordinary typhoid fever.

I shall have opportunities of showing you cases of typhoid fever where the disease runs its ordinary course. Typhoid fever may be the mildest of all diseases, or it may be the most virulent. In typhoid fever the special gravity of the case is usually due to severe abdominal lesions, grave pulmonary conditions, or marked nervous disturbances. It is very rare to meet with a case where, although the other symptoms may be marked, there is evidence of intense blood-dyscrasia associated with greatly-enlarged spleen, a tendency to jaundice, and the occurrence of hemorrhages and petechiæ. These are rare conditions in typhoid fever.

The patient has been on the same treatment which I mentioned at the last lecture. The observation of the case will be continued, and I shall report the result to you.

[After the last report the patient grew worse, the jaundice increased, and he again became dull and heavy. There was continued evidence of dyscrasia of the blood in extension of the subconjunctival ecchymoses and the formation of petechiæ. The patient gradually failed, and died December 29, 1886.

The autopsy revealed spots of caseating catarrhal pneumonia, chiefly in the left lung. The intestines showed the lesions of typhoid fever; the ulcers were evidently advancing towards cicatrization. Ulcerative endocarditis of one leaflet of the aortic valve was also found, the necrotic patch being one-third of an inch in diameter and involving the tissue to the depth of one line.

There was also cirrhosis of the liver, and its tissue was deeply stained with bile. The spleen was enormously enlarged, weighing thirty-five ounces. The pulp was quite softened.*]

PROFESSOR SCHROEDER, the eminent author, teacher, and operator, as announced by cable despatch, died on the 7th instant in Berlin. He was in the prime of life, and was prominent in the group of men who have extended the reputation of Berlin as a great medical centre. His clinic was largely attended, and his writings constitute valuable additions to the literature of gynæcology.

* The complexity and interest of this case are such that Dr. Pepper will make it the subject of a more complete report.

ORIGINAL COMMUNICATIONS.

GANGRENE AFTER TYPHOID FEVER.

BY L. HARRISON METTLER, A.M., M.D.

IT is surprising how little space has been devoted in English medical literature to gangrene occurring as a complication, or rather sequel of a complication, of typhoid fever. Though one of the most serious, it is also one of the rarest among the immense number of the sequelæ usually enumerated. In our systematic treatises it receives scanty notice. Reynolds, Bartholow, and Wilson do not allude to it at all; while Flint states that he never saw a case, and hence does nothing more than simply mention it; Murchison, our greatest authority upon typhoid fever, and Hutchinson, in Pepper's "System of Medicine," devote but a few short paragraphs to it; while Gross's "Surgery" does little more than state the possibility of its occurrence. The only approach to anything like an adequate account of the subject that I have found in English is the "Toner Lecture" delivered by W. W. Keen in February, 1876, before the Smithsonian Institute. In the hands of the French writers, however, the subject has received most exhaustive treatment.

I have notes of two cases, which differed somewhat, however, both in their etiology and pathology, so far as the clinical observation could determine, for it was impossible to obtain an autopsy in either instance.

The first was that of a little girl, 10 years of age, who had been under the care and successful treatment of a physician of this city during a long and severe attack of typhoid fever. The child's parents presented a good family history, and previous to the fever the patient had always enjoyed the best health. Convalescence had become fully established, and the child began to mingle again with her playmates in the open air, when one night she suddenly complained of a cramp with excruciating pain in the calf of the right leg. The family physician was summoned early the next morning, and in the course of the next twenty-four or forty-eight hours discovered the following signs of arterial obstruction and approaching gangrene: the skin grew dark and appeared unhealthy, and later exhibited a strong tendency to suppuration; the sensitiveness of the part was so intense that the slightest touch caused the child to scream with agony, this hyperæsthesia extending even to the tips of the toes, but gradually diminishing as the mortification became more pronounced; the local temperature below the knee was lower than normal, while the constitutional temperature remained as in health except at night, when it rose slightly; the pulse was feeble, but regular; no signs of endocarditis or special heart-lesion of any sort; the general appearance of the patient was anæmic.

When I first had the opportunity of seeing the case, which was several days after the first appearance of these signs, the gangrene had made considerable progress and the line of demarcation was becoming well marked just below the knee. After the usual routine treatment for ordinary gangrene had been tried without any apparent improvement, it was finally decided upon to amputate, which operation was performed by Professor Pancoast, at the knee-joint. Six weeks later the child died of exhaustion and impaired vitality.

The second case, though beginning as a *phlegmasia alba dolens*,—a sequel comparatively frequent after typhoid,—is nevertheless interesting as having shown just before the death of the patient a similar tendency to gangrene and consequently an implication of the femoral artery as well as the femoral vein. The patient was a woman upward of 70 years of age, whose right leg became swollen and œdematous during the course of the fever.

Very soon, small, rounded sloughs made their appearance here and there along the front of the thigh, while the limb below the knee began to assume the dark appearance previous to the onset of gangrene. Death from exhaustion and the effects of the fever occurred, however, before the gangrenous condition had made itself more pronounced. Compared with the former case, this one was not so striking, since the age of the patient, with its attendant atheromatous condition of the arteries and senile complications, affected more or less the etiological aspect of the gangrene itself. There was no autopsy.

Now, the question which I wish to consider here is, What is the immediate cause of this gangrene after typhoid fever? At the present time pathologists are generally agreed that the mechanical obstruction of an artery by a clot of blood is the special cause of the gangrene, but as to

the cause of the clot there is still the greatest diversity of opinion. An endocarditis sending forth emboli which finally become fastened in some narrowed portion of the arterial system and thus become the nuclei of the future thrombi, has been assigned as one cause. If this were the case we would expect the gangrene to appear in other parts of the body, say, for instance, the region of the head or of the arm, quite as frequently as in the lower extremities; but, as a matter of fact, out of one hundred and twenty-six localities affected in the cases cited by Dr. Keen, seventy-seven were in the extremities, of which seventy-two were in the legs. Furthermore, endocarditis is a very rare complication of typhoid fever (Wilson). In neither of the two cases reported above could the slightest symptoms of it be detected.

The combined effect of (*a*) "the altered blood," (*b*) "the weakened heart," and (*c*) "the mechanical difficulties in carrying on the circulation, especially in distant parts," has been considered as the cause of the clot. While these are undoubtedly powerful factors in assisting in its formation, yet it does not seem to me, when we study carefully the history of all the cases thus far reported, that any one of these conditions, or even all three combined, are immediately the cause of the clot. These conditions are more or less present in other severe forms of fever, such as pyæmia, puerperal fever, diphtheria, etc., and yet mortification of extensive areas due to an arterial obstruction is never so imminent as in typhoid fever. In the latter these conditions are very constant and well marked; but the gangrene, as Dr. Keen truly says, "is happily a rare complication." Let us consider for a moment or two each of these conditions separately. In the first place, *as to the blood.*

Barié, writing in 1884 for the *Revue de Médecine*, stated that the spontaneous occlusion of an artery by what Virchow calls "marasmic clots," or clots due simply to a certain condition of the blood, "is almost impossible" in typhoid fever, because of the peculiar kind of change in the blood of that fever, represented by a "diminution of the hæmoglobin, of the red corpuscles and plasma." And, again (I quote from Green's "Pathology," page 214), "To whatever cause it may be due, an increased tendency of the blood to coagulate is probably *never more than a predisposing cause of thrombosis.*" Thus the "altered condition of the blood," aside from the fact of its bearing a specific poison of a high degree of virulence, cannot be accepted as any more than a predisposing cause of thrombosis, especially if the endothelium of the arteries remain intact, a condition of things upon which the continued fluidity of the blood is especially dependent.

Secondly, as to the weakened heart, it needs but a moment's reflection to understand that this also is nothing but a predisposing cause in producing a retardation of the blood-current.

Thirdly, as to the mechanical difficulties in carrying on the circulation. This and the weakened heart condition act much in the same way to produce a stagnation of the blood-current, a distended condition of the arteries, and an impaired nutrition of the arterial walls through a consequent abnormal condition of the vasa vasorum, the whole resulting in an arteritis of a degree more or less severe. But how are we to explain the tendency to gangrene which so generally accompanies typhoid fever,—a fact on which M. Behier laid marked stress so long ago as 1857,—and its singular absence in other diseases in which arteritis of the same sort ought frequently to obtain, seeing that in them this condition of the heart and circulation is almost as common as in typhoid fever? It seems to me more reasonable to assume that the infectious material floating in the blood of a typhoid-fever patient possesses such a high degree of virulence as to act more readily upon the coats of the artery, which are already much diminished in vitality by the two mechanical causes just cited. But of this I will speak again, merely wishing to point out here the real influence of these mechanical forces in producing the gangrene.

The more I have studied this question, the more have I been convinced that the production of arterial thrombosis and consequent gangrene in typhoid fever is due in by far the greater majority of cases to an endarteritis assisted by various mechanical factors, but only in the same way that any attack of disease is assisted in its onset by a general cachectic condition of the system at large. I repeat, the immediate cause of this endarteritis is in all probability

the fever-poison in the blood in a condition of extreme virulence. That this is the state of the blood and its effect upon the inner lining of the arteries is established by the "almost constant muscular degeneration" which is so peculiar to typhoid, and which has been attributed to an *inflammatory obstruction* of the arteries supplying the muscular tissues. In this way do Hayem and Martin explain the myocarditis and consequent softening of the heart-muscle. Giraudeau attributes the degeneration of the general muscular system to an incipient myositis, and of the various viscera to the hemorrhagic infarctions, all due to the same cause,—viz., a primitive obliterating arteritis, produced by the highly poisonous condition of the blood. Many other authorities substantiate the same view.

Furthermore, we have cases reported of many other diseases in which arteritis has been attributed to this poison floating in the blood: for instance, variola (Brouardel), diphtheria, marsh miasm (Lancereaux, Verneuil), tuberculosis (Lancereaux), syphilis, and even rheumatism; so that inflammation of the arteries due to this cause is not such an uncommon affair; and how much more would this seem likely to be the cause in such a disease as typhoid fever, undoubtedly produced by one of the most noxious poisons that we know of!

Of one hundred and thirteen cases collected by Dr. Keen, he finds it seldom stated that the arterial walls were diseased. This fact might easily be accounted for by the comparatively incomplete autopsies that were often made in these cases, and by remembering that it requires but a very slight degree of inflammatory impairment of the arterial walls to produce a clot in blood already predisposed to that accident,—indeed, so slight as to be easily overlooked in a general autopsy.

Physiologists tell us that spontaneous coagulation of the blood is prevented in some way by the integrity of the arterial endothelium, and that clotting during life is associated with abnormality of the wall of the vessel in which it occurs (Burdon Sanderson). In speaking of thrombosis, Green states that "abnormality or removal of endothelium is the essential condition" of its occurrence. Hence in Dr. Keen's cases it is difficult to harmonize the presence of the clot with the *reported* healthy condition of the arteries in so large a proportion of them. Trousseau and many other authors are right to a certain extent in attributing the arteritis, when present, to the irritating action of the clot, after the manner of a foreign body. The inflammation is undoubtedly enhanced by the presence of the thrombus after it has once made its appearance, but the explanations of these authors as to the cause of the first appearance of the clot seem to me to be far from adequate. Among those who support the view of a general primitive arteritis occurring in typhoid fever, based upon autopsies made by themselves, we may mention the names of Gigon, Hayem, Patry, Larroque, Behier, Bourdeau, Mercier, Masserell, and others. The site of the clot is determined by causes of a mechanical nature, chiefly by the stagnation and retardation of the blood in the lower extremities. When the patient has reached such a degree of convalescence as to begin to walk about, the poisoned blood has special opportunity to produce its evil results in the most distant parts of the circulatory system, being there held in prolonged contact with the arterial walls, and assisted at the same time and in the same place by the pressure upon them. If the mechanical causes were in this respect alone responsible, why does not the gangrene appear earlier in the course of the fever, when the vitality of the blood and the force of the circulation are at their lowest ebb? Why do we not also have it appearing more frequently in the back, where the blood-stasis is assisted by the prolonged dorsal position of the patient? The bed-sores of this region have no place in this discussion, since they consist of a superficial gangrene produced by direct outward pressure of the superficial arteries, closing them, and thus cutting off the nutrition of the part.

In conclusion, I will repeat that gangrene as a sequel of typhoid fever is due to mechanical obstruction of an artery producing dry gangrene, or of an artery and vein producing moist gangrene by coagulation of the blood; and that this coagulation, while powerfully assisted by causes of a mechanical nature, is primarily due to an arteritis and abnormal state of the endothelium, brought about by the irritating action of the intense fever-poison floating in the blood.

1938 North Broad Street, Philadelphia.

A CASE OF EPILEPSY APPARENTLY DUE TO GENITAL IRRITATION, AND CURED BY CIRCUMCISION.

Read before the Philadelphia Neurological Society, December 27, 1886,

BY WHARTON SINKLER, M.D.

MORE or less difference of opinion exists as to the influence of peripheral irritation in the production of epilepsy. It is not generally agreed that sexual excesses or irritation of the generative apparatus can alone cause true epilepsy; but most writers admit that self-abuse and excessive venery bear a large part in the etiology of the disease, and that, if once established, these habits tend to aggravate and render it more difficult of cure.

Gowers thinks that masturbation in boys is a frequent cause of fits, which, while not genuine epileptic seizures, are convulsions of a hystero-epileptic kind.

Irritation of the prepuce or of the glans penis, even when not associated with masturbation, is believed by many to be the source of divers reflex nervous disorders, including epileptic convulsions, and many operations of circumcision have been done to relieve these conditions, with varying success.

To add some testimony to the subject, I wish to report to the Society the following case of marked epileptic fits associated with irritability of the genitals, and in which the attacks ceased after the operation of circumcision.

Frank P., colored, æt. 3 years and 5 months, came to my clinic at the Infirmary for Nervous Diseases July 19, 1886. His parents are healthy, and have five other children; none of these have had fits, but one has had chorea. He was well until December, 1884, when he had two spasms. These were attributed to teething and taking cold. In January, 1885, he had another fit. The attack was marked, and lasted three or four minutes. Since that time he has averaged one fit a week. The attacks are severe, the convulsive movements being general, and afterwards he is dull and sleepy. For several days past he has had an attack every day.

The child is well nourished, and shows no sign of rickets except that he is backward in teething. He is intelligent, and talks freely. The prepuce is elongated and inflamed at the edges, but can be retracted over the glans. Any touch, however, brings on an erection of the penis. The mother says that he handles the penis frequently, and seems to have some discomfort about it.

He was ordered potassium bromide, gr. ii ter in die. In one week returned and reported having had one attack. The bromide was increased to gr. v given as before.

August 2. The boy has had thirty-five or forty attacks during the past weeks; some days twelve or fifteen fits. He has become unable to speak, and seems to have lost his intelligence. The genitals are very irritable; a touch of the penis makes it rigid. Circumcision was advised, and the operation was performed by Dr. H. E. Goodman on August 9. The bromide was continued in five-grain doses three times a day.

In the week after the operation was done he had two attacks. Since then there have been none. The bromide was taken for about three weeks.

I examined the child on December 27, and he seemed well. He was bright and active, and talked freely.

Gowers speaks of a case of epilepsy in a boy of 13 years who had twelve or fourteen attacks a day under various treatment. It was found that he was addicted to self-abuse, and a blister on the prepuce reduced the fits to from two to seven a day. Circumcision was then performed, and the attacks ceased at once and did not recur. This author advises circumcision in all cases of epilepsy when masturbation is suspected.

THE CARE OF PATIENTS OF DOUBTFUL MENTAL STATE, AND THE PRIVATE TREATMENT OF THE INSANE.

Read at a Joint Meeting of the Philadelphia Neurological Society and the Philadelphia Medical Jurisprudence Society, January 24, 1887,

BY JOHN A. CLARK, ESQ.

THE subject which I have selected for a short paper—The Care of Patients of Doubtful Mental State, and the Private Treatment of the Insane—is one deserving of more practical attention than it has yet received from the community.

There are a large number of nervous cases which appear to hover on the confines separating a morbid condition of mind from actual and pronounced insanity. In most of these cases it is a long time after the development of the early symptoms before the friends and family of the unfortunate patient can bring themselves to realize the gravity of the malady. What they require is some system of prevention which may arrest and ward off an impending derangement of the mental faculties. The patient requires rest and repose, the

absence of all surroundings that can awaken or continue care and anxiety, and a judicious treatment both of the mind and of the physical health.

For persons in such a mental condition there should be sanitariums, or health-resorts, where they would be subjected to such wise moral and physical discipline as would tend to promote their recovery. A separation from their family and friends frequently seems necessary to produce these results. Unfortunately, there seems to be but slight provision for such a class of cases.

Nothing can be more complex or unfathomable than the human mind. The moral treatment of the patient has more potency in promoting recovery than the administration of any drugs or medicines. The anxiety and solicitude of the family of the sufferer often appear to deprive them of the ability to deal with the exigencies of the case as well as comparative strangers might. Yet, when it fully appears that some important step should be taken, they feel the greatest repugnance to consigning the invalid to the walls of an insane asylum, especially when there is a reasonable doubt in their minds whether the person is really insane or not. It is for this very large class of cases that intermediate hospitals are required.

It is probably preferable that such hospitals should be maintained by and under the supervision of charitable corporations, under the wise management of competent and conscientious managers and trustees, although there can be no good reason why private individuals and specialists should not establish and maintain such retreats for those mentally affected.

Crowded asylums must certainly militate against the opportunities of recovery. The environments of the patient are bad. These massive structures, with their frowning walls and battlements, suggest to the unfortunate patient that he has been transferred from the freedom of his home to the desolate loneliness of the penitentiary. He is thrown in contact with the incurable and demented. Man is an imitative animal, whether his mind is clear and normal or diseased by hallucinations. There is certainly a contagion in being surrounded by persons indulging in every possible delusion. How much preferable, then, is the condition of the patient of doubtful mental state when sent for treatment to an institution which is exclusively devoted to the treatment of similar cases! Such a home now exists under the care of the Friends at Atlantic City, where pure air and cheerful surroundings have restored many persons suffering from nervous disorders to perfect health. Such institutions should be established either by the sea-side or in the country, where the patients may have ample opportunity for exercise and recreation in the open air. They should only contain a limited number of patients, and should partake of the character rather of large families. There should be no gloom about such homes, no barriers or walls, no appearance of restraint, nothing, in fact, to impress gloom and melancholy upon the inmates, but all that is cheerful and bright to allure them back, as it were, to mental health. There should be music and flowers, cheerful books, diverting amusements, together with a round of rational employments suited to the tastes of the different patients, which would tend to divert them from the melancholy suggestions of their own morbid thoughts. Above all, there should be intelligent management, and a recognition of the peculiarities and idiosyncrasies of each patient. The attendants should be persons of experience, cultivation, and refinement. They certainly would require the possession of some Christian fortitude to endure the vexatious exactions and irritating caprices of those they have in charge.

It has been said by a recent writer that it is difficult to draw the line between actual insanity and some acute nervous disorders, and therefore many cases have been consigned to an asylum for treatment which are entirely out of place in its associations or under its care. Acute cases of insanity and hybrid types of nervous disorder can be treated and cured without the unpleasant remembrance of an asylum and without the injurious results which sometimes follow the injudicious incarceration of sensitive patients.

It is this consideration which brings us to the conviction that there should be such intermediate hospitals as I have described. They would not interfere in any measure with the asylums now in existence. The care of incurable patients and the treatment of those who have not yet reached the incurable stage should certainly be separated. How much more essential is it, then, that those of a doubtful mental

state, where insanity is not well established, should receive treatment in intermediate hospitals!

The question now arises whether there is anything in the lunacy law of the State of Pennsylvania which prevents the existence of such intermediate hospitals, and, if there is, whether it would be wise to make some new enactments covering such cases. The act of Assembly of May 8, 1883, entitled "An Act relative to the Supervision and Control of Hospitals or Houses in which the Insane are placed for Treatment or Detention," has worked a great revolution in the supervision of this class of persons in the State of Pennsylvania.

This law has been supplemented by the Rules and Regulations of the Committee on Lunacy, which have been ordained by the Board of Public Charities and received the consent of the Chief Justice of the Supreme Court and the Attorney-General, according to the provisions of the act. This act, with the rules before referred to, provides for the granting of licenses for asylums, the admission of patients, and the supervision of such institutions. The personal liberty of the citizen is protected from the possibility of the detention of a sane person, and the management of the asylum is under such supervision as to prevent the abuses which have heretofore crept into some institutions.

This law is a highly commendable one, and the existence of the Committee on Lunacy is one that assures the public mind that institutions for the care and treatment of those deprived of reason are under proper supervision and control. Institutions or individuals complying with the requirements of this act are protected from all judgments against them for the detention of any person unless the judge, after trial and verdict, shall "certify that there was proof to his satisfaction that the party charged acted with gross negligence or corruptly, or that he acted without reasonable or proper cause, or was actuated by motives other than the good of the person restrained."

No person shall be received as a patient for treatment or for detention into any house or place where more than one insane person is detained, or into any house or place where one or more insane persons are detained for compensation, without a certificate signed by at least two physicians agreeably to the provisions of the act and rules heretofore mentioned.

Certainly nothing in this act provides that persons suffering from nervous diseases may not be treated in the intermediate hospitals; but if doubtful cases are so treated, the very doubt implies that receiving such patients for treatment may be an infraction of this law. Persons may voluntarily place themselves in asylums, and may be detained for the time they shall specify by an agreement signed by them at the time of their admission, but not exceeding seven days, and they may from time to time renew the authority to detain them for a time not exceeding seven days from such renewal. No agreement shall be deemed to authorize the detention unless signed in the presence of some adult person attending as a friend of the person detained, in the presence of and also by the person in charge of the house or the medical attendant.

Thus it seems that if there were an intermediate asylum unlicensed by the Committee on Lunacy in which there happened to be two doubtful cases of persons who should prove to be insane, the maintaining of such a house would be in violation of the law. No person could be received for treatment in such a house unless they had the certificate of two physicians as required by the act and rules.

A literal construction of the act would seem to imperil any managers or other persons who would establish an intermediate hospital of doubtful cases without the same rigid compliance with the law which is required of those keeping insane asylums. It is certainly worthy of the consideration of the medical profession and the Committee on Lunacy whether it would not be proper and expedient to secure some additional legislation to provide for hospitals of an intermediate character. One patient can be treated at home, or a physician could receive one such patient in his own house, but not more. It is doubtful whether it would not be ascertained on careful examination that any hospital provided for persons suffering with nervous disorders has at least two patients who are probably insane.

This subject does not appear to have received the consideration of the legislature when the act of 1883 was passed, and it is certainly worthy of discussion at the present time, which should be conducted

in a calm and dispassionate manner, with the hope of a solution which shall be beneficial to patients suffering with nervous disorders which are likely to affect, if unrelieved, the soundness of the mind.

REPORT ON OPHTHALMOLOGY.

BY ALBERT G. HEYL, M.D.,

Ophthalmic Surgeon to the Episcopal Hospital.

EYE-AFFECTIONS IN GONORRHŒAL RHEUMATISM.

DR. RÜCKERT reports the following case. Patient, æt. 29, acquired three years ago a gonorrhœal urethritis, and shortly after a slight eye-inflammation and articular rheumatism developed. During the succeeding two years a number of attacks of eye-inflammation occurred, the precise character of which is unknown. A year ago a new gonorrhœal infection occurred, and almost simultaneously with it fresh pain and swelling of the joints. Two months ago a slight iritis set in, which was cured in about a week. Eight days ago the patient acquired again urethral gonorrhœa, and presented himself at the clinic for eye-treatment. Status præsens: fresh urethral gonorrhœa; both lids swollen, red, with dried secretion clinging to them; conjunctiva in all points hyperæmic, but the palpebral conjunctiva and fornix specially involved; cornea and deeper parts intact. The urethral secretion showed quantities of gonococci, but repeated examinations of the eye-secretion by Professor Sattler failed to demonstrate a single one. Rückert thinks, therefore, that this must have been a gonorrhœal conjunctivitis which was independent of inoculation. Under treatment the inflammation subsided, but on the fourth day of the treatment an iritis developed in the right eye. This yielded somewhat to treatment, and then cyclitis developed, with pain, cloudy vitreous, etc. During this time acute rheumatic affection of various joints occurred, one after another being affected. Patient was dismissed, but two days later presented himself with fresh urethral discharges, apparently due in part to the urethritis not having been completely cured. There was also irido-cyclitis of the left eye, which rapidly yielded to treatment. To prevent recurrence of the cyclitis an iridectomy was made, which did not effect its purpose, for fourteen days after the operation, with simultaneous fresh increase in the urethral discharge, cyclitis again appeared. This was relieved, but again during the succeeding six months several attacks of joint-inflammation and recurrence of the eye-inflammation were observed.—*Klinische Monatsblätter*, September, 1886.

[In this case salicylate of sodium was employed, and evidently with little success. Perhaps the internal use of cubebs or copaiba, as suggested by Jaccoud,* would have succeeded better. The case suggests that in cases of recurring iritis or irido-cyclitis the therapeutics may be at fault, and that besides the local treatment a specific—though perhaps in the present state of medical science unknowable—remedy is required. The presence of the gonococci in the urethral discharge and their absence in the eye-discharge is an interesting fact, which may be studied in connection with the points brought out in the next article in this report.—H.]

PURULENT OPHTHALMIA AND ITS TREATMENT BY HOT-WATER APPLICATIONS.

Purulent ophthalmia is a disease of bacterial origin, and as such is of great interest to the general practitioner.

1. It offers an opportunity for studying the effects of micro-organisms on living tissue in a locality peculiarly favorable for observation.

2. This disease generally comes under the care of the general practitioner at its inception.

3. It very commonly results in blindness, and beyond question in many cases by reason of faulty or timid treatment.

In a paper read before the Medical Society of the State of Pennsylvania by Dr. Heyl, and printed in the *Archives for Ophthalmology* (September, 1886), attention was called to some results of recent mycological research in this disease, and the *rationale* of hot-water applications as a means of treatment. The following is a brief abstract:

1. The disease is due to the infection by a micro-organism known from the name of its discoverer as the "gonococcus of Neisser."

2. This gonococcus attacks the cylindrical epithelium of the conjunctiva, which practically may be considered as being confined to the *palpebral* conjunctiva. The latter is to be looked upon as the culture-

* See Philadelphia Medical Times, November 27, 1886.

ground of the coccus: hence the rule with regard to limiting applications of the nitrate of silver to this structure. This rule, developed by clinical experience, now finds a satisfactory explanation.

3. The growth of the coccus depends on the age and vitality of the cylindrical epithelium.

4. The coccus works its way or is swept into the connective spaces underneath the scleral conjunctiva. This is raised into mound-like prominences by the accumulating cocci; the coccus is carried into the corneal nutrient channels, and a species of necrosis is set up in the hard, unyielding tissue, as a result of which the corneal ulcer is formed.

Two distinct objects in the treatment are to be kept in view:

1. To stop the growth of the coccus.

2. To prevent the coccus accumulating in the cornea, where it does harm not by directly ravaging the tissue, but by blocking the nutrient channels and causing a necrotic ulcer.

The practical value of hot water and the *rationale* of its action in the treatment are then dwelt upon. The method of application is as follows. A basinful of hot water, as hot as the hand can comfortably bear, is placed near the patient, and a handful of absorbent cotton dipped in it and applied to the closed eyelid. As fast as it cools, which may be in a quarter of a minute, it is reapplied. The applications are kept up for five minutes at a time. Three times a day in cases of infants is usually sufficient, although they may be oftener used.

[This extended notice is introduced because the subject is one of great practical importance. These cases of purulent ophthalmia almost always come into the hand of the general practitioner at the inception, and beyond question many a case which has ended in blindness has been the result of the timid treatment which it has received. It is something, then, to know of a simple remedy like hot water, which any one can use, and which may tide the case along until skilled treatment can be procured. Not that other methods of treatment are discredited, nor that hot water will cure all cases. Confessedly the gonorrhœal ophthalmia of the adult is often not very noticeably affected by hot water: the reason seems to lie in the diminished vitality of the tissue-cells of the adult, in consequence of which they respond very slightly to the remedy. This disease of purulent ophthalmia is also very interesting from the mycological standpoint, and in this connection Professor Jaccoud's lecture on gonorrhœal infection (*Philadelphia Medical Times*, November 27, 1886) may be studied.—H.]

THE VISUAL CORTICAL CENTRE.

V. Gudden (Separat-Abdruck aus der *Zeitschrift für Psychiatrie*, Bd. xlii.) gives the results of experiments in cortical localization, from which the following is noted. 1. There do not exist strictly circumscribed areas of cortex cerebri which exclusively and under all circumstances possess definite function, although by no means is the existence of cerebral localization to be denied. At all events, there exist two principal areas (haupt regionen), one for sensation, the other for movement conceptions. 2. V. Gudden denies the existence of the visual centre of Munk, basing his opinion on the following experiment. The eye of a newly-born rabbit was enucleated; as the most of the optic-nerve fibres cross to the other side at the optic chiasm, so ought the supposed visual area on the other side in the cortex to become atrophic if such an area exist. This, however, did not occur. The optic nerve and the corresponding optic tract, with the corpus geniculatum externum and the uppermost gray cap of the anterior corpora quadrigemina, became atrophic, while an apparent atrophy of the occipital lobe was simply the result of displacement of the whole cerebral mass arising from the atrophy of the above-named parts and the orbital changes succeeding the enucleation. Anatomically, the two occipital lobes did not differ from each other.—*Centralblatt für Augenheilkunde*, July, 1886.

EXAMINATION OF THE EYES OF EPILEPTICS.

Schleick communicates the following results of the examination of one hundred and twenty-seven epileptics in the Stetten Hospital in Würtemberg. The majority of the cases suffered from simple typical epilepsy; in a few there were symptoms of cerebral and spinal disease. In ten cases there were anomalies of the eye-muscles: viz., four cases of strabismus convergens, three of divergent squint, two of very decided nystagmus. With reference to the pupillary reaction, in one case there was a decided difference in the width of the

pupils, the eyes being normal in other respects. In a second case there was only minimum reaction to light, but prompt contraction with convergence and accommodation. In nine cases the pupillary reaction to light was very slight, the eyes being normal otherwise. The result of the ophthalmoscopic examinations: In no case was there neuritis optici, choked disk, or pronounced atrophy. In a large number of cases paleness of the outer half of the optic disk was observed. In eight cases in which this was observed the functions of the eyes were preserved. In two of them there were evident hemiparetic symptoms, in a third disturbance of coordination, and in a fourth undoubted paralytic symptoms. In nine other cases the whole papilla was an opaque white, but no functional disturbance of the eyes existed. The whole number of cases in which the above-named ophthalmoscopic appearances were observed to greater or less extent were fifty-two. In one-fourth of them there was distention of the venous vessels.—*Klinische Monatsblätter*, 1886.

[Compare *Philadelphia Medical Times*, No. 500, article by Dr. Oliver.]

EYE-PARALYSIS IN A CASE OF MULTIPLE SCLEROSIS.

Thomsen (*Gesellschaft für Psychiatrie zu Berlin*) reports the following case. Patient, æt. 49, with symptoms of multiple sclerosis, could move his eyes easily to right, left, and downward, but scarcely above the horizontal plane. This defect in the upward movement was rather more marked in the left than in the right eye. The pupil reacted very slightly; both papillæ somewhat pale. The post-mortem showed multiple sclerosis of the spinal cord as far as the upper cervical portion; above this sclerotic patches could not be observed, but there existed a marked ependymitis of the fourth ventricle. The nerve-nuclei in pons and medulla were normal; this was particularly noted of the nuclei of the third nerves. On the other hand, between the cerebral peduncles just at the exit of the third nerves a gumma was found, which on the right side penetrated deeply into the peduncle, reaching the substantia nigra. The root-bundles of the right third nerve were much degenerated so far as they were embedded in the tumor. The left third-nerve bundles were intact.

Sections of the trunks of the third nerves showed the left one to be slightly, the right one greatly, degenerated. The superior recti muscles were normal. This, then, was *not* a case of associated paralysis, but a peripheral lesion, especially of the right oculo-motor. The fact that the great degeneration of the right and the slight degeneration of the left should have induced the same defective motion in both eyes, and had only affected the upward movement, is worthy of note.—*Centralblatt für Augenheilkunde*, 1886.

EYE-SYMPTOMS IN NUCLEAR PARALYSIS.

Schmidt-Rimpler reports the following. The patient, a girl, æt. 20, presented herself with right abducens paralysis. Later on came symptoms of bulbar paralysis; finally, total paralysis of the whole body and face-muscles. Post-mortem showed glioma of the pons, which had made its way into the crura cerebelli ad pontem and the pyramids. Choked disk was absent in this case, only a slight hyperæmia and clouding of the papilla making its appearance two days before death.

Uhthoff reports the following case. Patient, æt. 15, was affected with ophthalmoplegia externa. The movability of both eyes was almost completely gone, medium ptosis and slight paresis of both facial nerves. All other brain-symptoms were absent, and the general condition of health was normal. The affection had existed for three months, and did not seem to vary. In connection with this, Uhthoff demonstrated a specimen taken from a child, æt. 3, who died of general tuberculosis. During life, along with brain-symptoms, there was complete paralysis of both abducens nerves, paresis of both interni, the movements upward and downward also defective. The condition of the pupils normal. Post-mortem showed a tubercular tumor the size of a hazel-nut in the medulla.—*Centralblatt für Augenheilkunde*, September, 1886.

CONGENITAL ANOMALY AT THE POSTERIOR POLE OF THE EYE.

Birnbacher reports the following case. Patient, a man, æt. 21, with poor vision for distance, has $V = \frac{6}{36}$ in each eye when aided by concave 7 D. No scotomata, visual fields normal, refracting media clear. At the macula lutea of each eye there was a well-defined patch of pigment-alteration. The refraction of the patches was myopic,

but very much less so than the surrounding fundus, seeming to indicate that the patches were considerably elevated. The author considers the condition congenital by reason of the sharp outline of the patches and the absence of signs of inflammatory changes in the fundus. [The congenital character of this case may be doubted, although its exact pathology may not be clear.]—*Archives of Ophthalmology.*

FOREIGN BODY IN THE ORBIT.

Dr. Taylor, of Wilkesbarre, Pennsylvania, reports the following. The patient, a child æt. 20 months, in falling forward on the floor, struck his head on a pen-holder which he was holding in his hand. The mother stated that the pen-holder ran up into the left nostril and broke off. Three pieces were removed from the nostril, but later the left eye began to project from orbital inflammation, and the tissues about it became hard and swollen. Any attempt to open the lids seemed to cause great pain. Holding the head firmly between the knees, the lids were opened slightly by an elevator, and a small black object presented itself, which on extraction proved to be a part of the pen-holder, one and one-sixteenth inch in length, one-eighth of an inch in diameter at the smaller and three-sixteenths of an inch in diameter at the larger end. It had remained in the orbit about three weeks, causing intense pain and a high grade of inflammation. Subsequent treatment of instillations of atropine, lead-water and laudanum applications, free incisions into swelling, was followed by rapid recovery. —*Archives of Ophthalmology.*

THE EXOPHTHALMOS OF BASEDOW'S DISEASE.

Professor Hack, of Freiburg, reports the following interesting clinical experience. A lady from early youth had been affected with marked exophthalmos and widely-dilated pupil. This originated in connection with marked occlusion of the nares. The heart was in normal condition until the seventeenth year, when, apparently without cause, darting pain and palpitation in the heart-region developed, which were relieved by digitalis. Pulse 100. The symptoms increased, and the thyroid gland enlarged considerably. The nasal obstruction increased, and, as this seemed to depend on hyperplasia of the turbinated tissue of the two lower and middle turbinated bones, the right lower turbinated tissue was cauterized. On the following day the exophthalmos on this side had nearly disappeared. Cauterization was then made of the left lower turbinated tissue, and the exophthalmos on the left side yielded, but more slowly than the right. The pupils, however, were not affected. The heart-palpitations after a time disappeared. Hack thinks we have in this a clue to the etiology of certain cases of Basedow's disease: viz., an abnormal state of certain peripheral terminal sympathetic organs located in the turbinated tissue.—*Centralblatt für Augenheilkunde*, September, 1886.

TRANSLATIONS.

BOUISSON ON THE DIRECT SUTURE OF THE MEDIAN NERVE.—At a recent meeting of the Biological Society, M. Bouisson showed a patient in whom he sutured the median nerve, and made some observations upon the interesting question of nerve-repair after section. In the wound, above the wrist, there had been a section of the median nerve, the superficial tendons of the forearm, and of the ulnar artery, which was ligatured at both ends. The wound had healed by first intention. Before the operation there was complete insensibility on a level with the palm of the hand. The thenar eminence and the thumb retained their sensibility, though voluntary movement of the muscles of the former was totally abolished. On the morning after the operation, sensibility to contact had returned. Nevertheless, the points of the æsthesiometer were not perceived.

On the following days there were spontaneous pains, beginning at the suture and radiating into the fingers innervated by the median. On the 21st of November flexion was impossible in the thumb, and almost so in the other fingers; faradic contractility was suppressed. On the 23d the patient was able to make a few slight movements with the thumb; sensibility unchanged. On the 27th the patient was able to bring the thumb and index into contact, and also to execute a few rotary movements with the thumb. The prick of a needle

showed that sensibility existed throughout the whole hand, but was less pronounced in the regions corresponding to the median; sensibility to heat was abolished on the middle finger and the index. The second and third phalanges of these fingers were insensible to heat, and apparently so to pain; the thumb retained its sensibility to both heat and pain. On the application of the æsthesiometer, whatever the space intervening between the points, the patient felt only a prick, and that even when one of them was placed on the palmar face of one of the phalanges of the three fingers innervated by the median and the other on another phalanx of the same finger; the effect was the same on the palmar teguments innervated by the median, and also on those of the thenar eminence.

A minute electric examination of the patient was made at the Salpêtrière on the 27th of November, by M. Vigouroux, with the following result. On the healthy side a galvanic current from sixteen elements, $30\frac{10}{1000}$ ampères, one pole on the back of the neck and the other in the fold of the elbow, produced contractions, and, with the negative pole, of the flexors. On the diseased side, the conditions being the same, but with twenty elements, $30\frac{10}{1000}$ ampères, there was contraction only in the flexors. With faradic currents, one pole on the back of the wrist and the other on the muscles of the thenar eminence, the patient felt the current, but there was no contraction, even with the maximum intensity. Galvanic currents produced contraction of the abductor and movements of the thumb; with the poles brought as near together as possible on the thenar eminence, there seemed to be a feeble contraction of the abductor on inversion. One pole placed on the top of the thenar eminence and the other on the external border of the metacarpal elicited by a brisk inversion an almost imperceptible movement of abduction with a current from fifty Leclanché elements, $33\frac{10}{1000}$ ampères. Mechanical excitability remained intact. On the whole, the absence of faradic reaction and the maintenance of mechanical excitability indicated degeneration of the muscles of the thenar, with the exception of the abductor. Nevertheless, the patient presented one of the signs considered as pathognomonic of nervous reunion: pain in the region of the median nerve when the suture was pressed upon, and also spontaneous pains during the first days.

On the 2d of December the two points were perceived in places on the thenar eminence, especially on a line following the border of the metacarpal. Sensibility to the points was totally abolished on the index, middle finger, and thumb. Sensibility to heat and to pain existed on the thumb, the thenar eminence, and in the palm of the hand; it also existed in a less degree on the first phalanx of the index and radius, but was not perceived on the other phalanges of these two fingers. This test was made with a copper ball heated with gas. The patient was able to approach his thumb a little beyond the second phalanx of the index, showing feeble progress. Atrophy of the thenar eminence was now well marked, and there was also a certain livid aspect of the skin of the fingers innervated by the median, a state comparable to local asphyxia in the extremities, and flexion of the second and third phalanges impossible. The case was curious, as it presented an almost immediate partial re-establishment of the nervous functions, while those functions were found to be profoundly disturbed and the nerve degenerated. The apparent partially-restored sensibility and mobility, and the pain in the fingers innervated by the median on pressing the suture, and also spontaneously, are signs of the so-called primitive reunion of the nerve; the test for degeneration and the atrophy of the thenar eminence are proofs of degeneration. Absence of sensibility to the æsthesiometer is a certain sign, according to M. Tripier, that the sensibility found in the region of the median is a borrowed sensibility.

Mouth-Disease of Animals.—At the Academy of Sciences, M. Magitot described a serious malady, similar to scurvy, which had been noticed in certain reptiles, and which was designated by the name of *mal de gueule*. It was characterized by inflammation of the mucous membranes of the mouth, by abscesses, ulcerations, adenitis, etc. The causes of the affection are similar to those that bring about scurvy, — namely, humidity, overcrowding, etc. The buccal mucus contains numerous bacilli, probably of a pathogenic character.

EDITORIAL.

THE THERMAL DEATH-POINT OF PATHOGENIC ORGANISMS.

THE address of Dr. Sternberg before the College of Physicians on Wednesday evening was a notable contribution to our knowledge of the life-history of certain microbian factors of disease. The determination of the thermal death-point of disease-germs has a very important bearing upon methods of preventive medicine, and possibly of curative therapeutics. No bacteriologist has had more extended experience in this special line of investigation than Dr. Sternberg, and the results of his researches may be accepted as exact and conclusive.

The experiments upon which the conclusions of the eminent investigator are based have been pursued by him for a number of years, and have been variously modified and improved. The method used at present is to expose a pure culture of the organism to be tested for a definite period of time to exactly ascertained temperatures, and note the result upon the power of development of the organism when the latter is subsequently placed under favorable conditions for growth. By repeating the experiments many times and checking each series by a control-experiment, the results obtained must approach absolute exactness.

While in Dr. Sternberg's previous experiments a pretty nearly uniform thermal death-point was determined for a number of pathogenic micrococci, it was generally believed that spore-forming organisms required a higher temperature for their destruction, and that the spores themselves required the influence of a temperature reaching that of boiling water, or even higher, for a prolonged period. Even in cases where the thermal death-point for the developed organisms was low, as shown by Chauveau to be the case with anthrax-bacillus, the temperature required for the destruction of the spores of this organism, according to Sternberg's experiments several years since, equalled that of boiling water (100° C.) maintained for several minutes. The spores of various non-pathogenic bacteria, such as bacillus subtilis, Koch's "garden-soil bacillus," etc., have proved more resistant, requiring higher temperatures or longer exposure to the destructive action of the heat. The varying resistance of the spores of bacillus subtilis to the temperature of boiling water has generally, since Tyndall's admirable experiments, been attributed to the desiccation of the spores. There is also a general belief among bacteriologists that desiccation of the spores of other organisms increases their resistance to the germicidal action of heat or other disinfectants.

In view of the important relations of the recently discovered bacillus of typhoid fever, and the general acceptance of its spore-forming nature, it was important to determine, especially for purposes of disinfection, whether the spores of this organism were more or less resistant to the lethal influence of heat than those of some of the other bacteria mentioned. Sternberg, in a conclusive series of experiments, has now shown that the thermal death-point of the typhoid bacillus, including spores (assuming that its spore-formation is demonstrated), is quite low and entirely within the range of practical measures of disinfection. Similar observations upon the spirillum of Asiatic cholera have likewise shown that a comparatively low degree of heat is sufficient to render it absolutely innocuous.

The thermal death-point of the various organisms is given in the following table. With a few exceptions noted, the determi-

nations were made by Dr. Sternberg. The time of exposure was ten minutes, except in the observations on the cholera-spirilla of Koch and Finkler and Prior, for which an exposure of four minutes sufficed to destroy the life of the organism. The experiments on tubercle-bacillus were made by Schill and Fischer, under Koch's direction, the exposure being for five minutes. Dr. Sternberg does not consider the experiments of Schill and Fischer conclusive, and is now submitting the question to further investigation.

Organism.	Thermal Death-Point. Cent.	Fahr.
Typhoid-bacillus	56°	= 132.8°
Cholera-spirillum (comma-bacillus of Koch)	52°	= 125.6°
Cholera-spirillum of Finkler and Prior	52°	= 125.6°
Cholera-bacillus of Emmerich	62°	= 143.6°
Anthrax-bacillus (without spores, Chauveau)	54°	= 129.2°
Tubercle-bacillus in fresh sputum (Schill and Fischer)	100°	= 212°
Bacillus of glanders (Löffler)	55°	= 131°
Bacillus of mouse septicæmia Bacillus of Rouget Bacillus of Schwein-Rothlauf	60°	= 140°
(These three organisms appear to be identical. They are said to form spores.)		
Brieger's bacillus (from fæces)	62°	= 143.6°
Bacillus of green pus	56°	= 132.8°
Friedländer's bacillus (so-called pneumococcus)	58°	= 136.4°
Bacillus of foul-brood	100°	= 212°
Staphylococcus pyogenes aureus	58°	= 136.4°
Staphylococcus pyogenes citreus	62°	= 143.6°
Staphylococcus pyogenes albus	62°	= 143.6°
Micrococcus of osteomyelitis	58°	= 136.4°
(Probably identical with Staph. aureus.)		
Streptococcus of erysipelas	54°	= 129.2°
Micrococcus tetragenus	60°	= 140°
Micrococcus Pasteurii (Sternberg)	60°	= 140°

No more important investigation into the nature and life-problems of disease-germs has ever been undertaken and successfully carried out in this country, and the College of Physicians is to be congratulated upon its enterprise and good fortune in being the medium through which these researches were first given to the profession.

This communication seems particularly appropriate following Dr. E. O. Shakespeare's report of the results of his personal investigations on cholera, both in Europe and in India, a summary of which has already appeared in these pages.

THE CHOICE OF ANÆSTHETICS.

ON the 9th instant a death occurred in this city, during chloroform-anæsthesia, which directs attention most forcibly to the oft-repeated lesson of the dangers from chloroform, even when employed with greatest care. The patient was an attaché of a menagerie, and a professional lion-tamer, and was apparently of robust constitution and excellent health. He applied for treatment for a false anchylosis of his hand, which had followed an injury some months before. In order to break up the adhesions he was brought before the class at the Medico-Chirurgical College by Professor Pancoast, and the physician who had charge of the anæsthetic was directed to administer only sufficient chloroform to induce primary anæsthesia, during which the adhesions in the wrist could be broken by passive movements. The man complained of the manipulations very much, and at the last inspired the chloroform hurriedly in order to come rapidly under its influence. It was observed that his face assumed a pallid look and his pulse was imperceptible, and, in spite of efforts at resuscitation, he died almost instantly.

At the post-mortem examination it was found that the heart was fatty, and the coroner's physician attributed the fatal result to cardiac failure. He had also cirrhosis of the liver and kidneys.

This distressing occurrence, when taken in connection with the numerous deaths previously reported from chloroform, suggests the question, Is there sufficient discrimination exercised by surgeons in the choice of an anæsthetic for each operation, or are they largely governed by habit and convenience? One surgeon always employs ether, another always uses chloroform, another adopts the A C E mixture of the London hospitals, while others are partisans of the bromide of ethyl, bichloride of methylene, nitrous oxide, or hypodermic injections of cocaine. It is ad-

mitted, however, that there is a sliding scale in the risk of inducing anæsthesia by these agents, at one end of which is the nitrous oxide gas, at the other is chloroform-vapor.

Attention has been repeatedly called to the fact of the extraordinary density of the vapor of chloroform; and its effects in displacing oxygen in the air-vesicles of the lungs (and probably in the red blood-corpuscles) may be in some measure dependent upon this physical fact, as suggested by Dr. William H. Greene in a communication to the *American Journal of the Medical Sciences* some years ago. When injected into the jugular vein, chloroform kills animals by arresting the heart's action and destroying its muscular irritability. In fact, as pointed out by Reichert, all anæsthetics containing a halogen act as cardiac depressants. Therefore, when chloroform is administered, some precautions are necessary to prevent its inhalation in a state of too great concentration and without sufficient dilution with atmospheric air. The use of an apparatus like that of Clover, which allows an admixture of only three per cent. of chloroform-vapor, would greatly reduce the risk from the use of this agent.

Ether, on the other hand, needs no dilution, and, if pure, the vapor may be inhaled almost with impunity, with ordinary care, even in the hands of one not particularly skilled in the use of anæsthetics. It is therefore a safer agent to intrust to the hands of the inexperienced hospital resident than chloroform, ethyl bromide, or bichloride of methylene.

Since accidents during the administration of chloroform usually occur in cases of trifling operations, which all concerned seem anxious to finish with despatch, such as tooth-pulling, surgical manipulations, and opening abscesses, it is worth while to inquire whether or not the fashion of employing a single anæsthetic for all classes of cases should not be abandoned, and recent investigations upon the subject be taken more notice of by the profession generally than seems to be the case at present.

More than a year ago, Brown-Séquard proved that general analgesia could be produced by directing a stream of pure carbonic acid gas upon the larynx at the end of inspiration. Bert has reported interesting and suggestive experiments upon nitrous oxide given under increased atmospheric pressure. Esdaile and others have demonstrated that hypnotism can be applied so as to take the place of an anæsthetic even for large surgical operations, and it has been used successfully during parturition. (This field invites further investigation.) Corning has demonstrated that by incarcerating hypodermic injections of cocaine, even major operations may be painlessly performed. Bonwill, of this city, has established the fact that temporary general anæsthesia can be obtained by such a simple and inexpensive expedient as rapid breathing. Professor Matthews, of Louisville, Kentucky, in a recent report to the State Society, advocates the use of whiskey, and declares that in rectal operations the stupor caused by this agent affords all that is desired in the way of anæsthesia. Opium-narcosis might also be occasionally resorted to, as well as other expedients in use before the introduction of modern anæsthetics. Modern improvements in the preparation of apparatus for the administration of nitrous oxide gas should lead to its more general use by the medical profession. We would urge upon surgeons the necessity of selecting the anæsthetic appropriate to the individual case as carefully as they would prescribe any other therapeutic agent. We do not say that chloroform should never be given; but that, when used, it should be with a full sense of the increased danger, and with the deliberate conviction that any other anæsthetic would be less suited to the patient to be operated upon. The dictum that ether must not be given

to persons with renal disease, or chloroform to persons with cardiac degeneration, must not be taken too absolutely or too literally; in point of fact, the patients who are treated at our clinics rarely have hearts or kidneys to which exception could not be taken by the pathologist.

With regard to the case above mentioned, there can be no doubt that the sudden death was due to the diseased condition of the viscera, as complete anæsthesia was not induced or attempted. Professor Pancoast ordinarily is an ether-giver, but uses chloroform for slight operations, merely to benumb the sense of pain without producing loss of consciousness, in the manner in which it is commonly used during parturition.

EXPERIMENTS UPON THE VIRUS OF RABIES CANINA.

BY invitation of the Philadelphia Academy of Surgery, Dr. H. C. Ernst, of Harvard University, has presented the results of his personal investigations upon Pasteur's method, which in the main confirm the statements made by Pasteur with regard to the effects of inoculations, the existence of some specific virus in the spinal cord of rabbits dying of rabies, and the modifying effects of desiccation and heat. The interesting discussion upon this, which is probably the most important paper read before the Academy this winter, appears in another column.

EXTIRPATION OF THE LARYNX.

AT the University Hospital, last week, Professor Agnew removed the larynx from a patient of Dr. Solis Cohen, for malignant growth involving one arytenoid cartilage but not encroaching upon the glottis. The patient died on the fourth day, with exhaustion. By a singular coincidence, similar cases are reported in the correspondence from London and Baltimore in our present issue.

NOTES FROM SPECIAL CORRESPONDENTS.

LONDON.

HOW the magnificent bequest of Sir Erasmus Wilson to the Royal College of Surgeons ought to be disposed of is one of the questions which is exciting most interest in medical circles here at the present time. That it has excited so much interest is perhaps not altogether to the taste of the Council of the College, who, it is evident, would have much preferred to have been left to expend it after their own fashion, which was, it appears, to devote the whole sum, about two hundred thousand pounds sterling, to the enlargement and maintenance of the museum. This museum is already famous; every medical visitor to London makes one of his first visits to the well-known building, with its heavy Grecian portico, in Lincoln's Inn Fields, where so many valuable specimens have been gathered around John Hunter's collections as a nucleus. The cost of maintaining the museum has been considerable, and has fallen entirely upon the College of Surgeons. The income of the College has been chiefly derived from the fees paid for its diplomas. The Council deliberates in secret, and only such reports can be published by the press as the officials see fit to furnish. It is, however, impossible to expect that secrets which are known to so large a body should long remain secret, and it became known at the beginning of December that the Council had gone so far as to order plans to be prepared for a great extension of the museum, which, according to calculations made by persons acquainted with the existing buildings and the disposition of the property of the College, would swallow up the whole of the Erasmus Wilson bequest. It is understood that an alternative scheme, drawn up by Mr. Jonathan Hutchinson, who is a member of the Council, would have provided all the additional space really needed for the museum at an outlay of one-tenth of the sum. Mr. Doran has written a letter to the *British Medical Journal*, in which he states very positively that no action has been taken by the Council beyond the adoption of a report from the "Committee on the Practicability of Adding a New Wing to the Museum," which report asked for enlarged powers; and, as Mr. Doran has exceptional opportunities for obtaining information of what goes on at the Council, his statement is probably correct. Whether this committee is the same as that appointed to report on the disposal of the bequest has not been stated, but to a committee thus described a very remarkable memorial, presented to the Council on January 13, was referred. This memorial was signed by representative men in medicine, physiology,

and chemistry; by such physicians as Gull, Andrew Clark, Hughlings-Jackson, David Ferrier, and Lauder Brunton; by such surgeons as William Bowman, Henry Thompson, and Erichsen; by such physiologists as Burdon Sanderson, Michael Foster, and Schäfer; by biologists such as Huxley, Moseley, Ray Lankester, Romanes Hooker, and Thiselton Dyer; by physicists and chemists such as Tyndall, Müller, Groves, and Thomas Stevenson; and by such workers in sanitary science as John Simon, Corfield, Cory, and Watson Cheyne. This memorial urged that the bequest should be devoted to founding an institution, under the direction of the College, which should have for its object physiological and pathological research. It will be practically impossible for the Council to ignore the prayer of a memorial signed by such men in the way in which it ignores the recommendations of the Members and Fellows of the College, and Dr. Samuel Wilks, who got up the memorial, has done a great public service, because he has insured that the whole subject shall be thoroughly discussed and examined.

Much may be said both for and against the foundation of such an institution as that contemplated by the memorialists, but it is hardly to our honor that we have not in England a single laboratory where pathological research can be carried on, except the laboratory of the Brown Institution, which is, or ought to be, a veterinary laboratory. There are class-rooms for pathological histology at the medical schools, and the registrars of the hospitals have rooms where microscopical preparations can be made; but this is all.

Mr. Lawson Tait, whose tenure of office as President of the Gynæcological Society has just expired, delivered a valedictory address breathing defiance. The chief *casus belli* was the attitude of certain well-known gynæcologists with reference to the operation for the removal of the uterine appendages; but, in the words of the Shakespearian stage-direction, there were other "alarums and excursions." The vials of his wrath were especially poured out upon Sir Spencer Wells, Dr. John Williams, and the *Lancet*. Mr. Tait particularly objected to the application of the term "spaying" to the operation in question, and if it is only performed when the ovaries are diseased, the objection appears sound; but, so far as I have been able to follow the controversy, this matter of observation is in fact the point in dispute. From a practical point of view, the chief upshot seems to have been that it is now very clearly laid down that those who practise the operation should take the greatest care to explain fully to the patient and her friends that sterility, if it does not already exist, will be produced by the operation. According to Mr. Tait, this sterility does not involve permanent loss of sexual appetite.

The announcement that Sir James Paget, the new President of the Pathological Society of London, would deliver an address on taking the chair for the first time, drew a large audience to the meeting of the Society on January 18. Sir James Paget is always suggestive, and it is a rare treat to listen to one of his thoughtful, closely-reasoned addresses, where every word is well chosen, every sentence neatly rounded, and the whole is delivered with dignity of manner and the most exquisite modulation of voice. It was characteristic of him that though he is, as Sir Joseph Lister said afterwards, the Nestor of the profession, yet he did not look back. "I hope I shall not prove myself unwise," he said, "if I do not take for the subject of my address that kind of knowledge in which alone I might claim superiority over my hearers,—namely, the personal memories of the far-distant past." Pathology, he reminded his hearers, —and it is devoutly to be hoped that his words may not be forgotten,—is something more than morbid anatomy; there is in it work also for the physiologist, the clinical observer, the experimentalist, the microscopist, the statistician, the chemist, the naturalist, the historian, and the psychologist. "Complete pathology," he said, "must be constructed from the work of all these;" they are mutually dependent, mutually corrective; none can alone suffice, and none can safely be neglected. The address was chiefly occupied with the results which might be attained in pathology from practice,—practice studied with the scientific mind, as Edward Jenner studied it,—and especially with the necessity for more minute and accurate clinical observation. In an eloquent peroration he referred to that sad defect of old age, indifference or dislike to the changes which come of the increase of knowledge. "One sees that, as men grow old and wish for rest, they are prone to ask, Where are we to stop? I do not know, more than this: that we must not stop where we are."

At the same meeting of this Society Dr. Ord showed a number of fragments which had been painlessly expelled from the bladder in the case of an old gentleman who had been laid up for the previous four months in bed, owing to thrombosis in one leg. There could be no reasonable doubt that the calculus had undergone spontaneous disintegration. The urine contained sugar, but in varying amount, and Dr. Ord attributed the disintegration in this case to the alterations in the specific gravity of the urine, which, in his opinion, would lead to changes in the laminæ of the calculus analogous to those produced by drying, a process which, as is well known by curators of museums, is often followed by fracture of the calculus.

Mr. Jordan Lloyd has reported in the *Lancet* a case in which he extirpated the larynx for intra-laryngeal growth. The larynx was

freed from all lateral attachments, and the trachea rapidly cut across with Paquelin's cautery, and into the cut end a curved glass tube was at once introduced for about two inches; the administration of chloroform was continued through the tube, while the patient's head was allowed to hang over the table, so that all the blood gravitated into the nares and mouth; the larynx was excised with scissors so as to diminish the amount of hemorrhage. The trachea was sutured to the skin. The patient died of broncho-pneumonia on the sixth day. Two cases of excision of the larynx for malignant disease have been recently performed in London, and in both the patients made a good recovery. One of the patients is a well-known barrister, who has since received a judicial appointment, the duties of which he is at present discharging.

Dr. Octavius Sturges has again taken up his parable on the subject of chorea, and this year estimates that at least one-fourth of the cases which come under his observation are due to some fault in the schools, the causes being over-schooling, home-lessons, excitement in schooling, and caning. The evil he traces to the teachers not differentiating their material in respect of ability, temperament, bodily health, and home circumstances. Whether there is more chorea now in London than there was before education was compulsory it is difficult to prove; but it is quite certain that it is far more often attributed by the parents to something that has happened at school than used to be the case.

It is announced that considerable supplies of strophanthus have now been received in this country from East Africa, and its therapeutic use is extending. The preparation heretofore used for dispensing has been a tincture of the same strength as tincture of digitalis: that is to say, one in eight. The ordinary dose of this tincture of strophanthus was two to four minims; but Professor Fraser, who introduced the drug about a year ago, now recommends as more convenient a tincture of one in twenty, of which the dose will be from five to ten minims. He still recommends that the seeds alone should be used, and that they should be first exhausted with ether to remove the large quantity of inert oil, which, if retained in the tincture, causes it to become opalescent with water; this process, however, adds very seriously to the cost of the preparation, and many pharmaceutical chemists consider it an unnecessary refinement, as the opalescence produced does not materially detract from the elegance of the preparation when dispensed. Professor Fraser finds that the amount of the alkaloid which is contained in the pericarp and the comose appendices of the seeds is not only small, but inconstant, so that preparations made from them would not be of uniform strength.

Dr. Pedley, of Rangoon, gave a curious description of the customs connected with parturition among the Burmese. The woman is secluded in a small room, where a fire is lighted after every aperture has been closed; a scarf is tied tightly around the body above the umbilicus, to prevent the uterus mounting into the chest, while the midwife presses violently on the abdomen; when the head begins to descend, the woman is placed on her back with her knees drawn up, and the midwife, if the woman is a primipara, incises the perineum with her thumb-nail or great toe-nail. As soon as the head is born, the child is dragged out with all possible speed, and the placenta extracted by traction on the cord; if this fails, it is extracted piecemeal with the hand. The only method of assisting the mother is pressure on the abdomen, and for this purpose a plank is placed across the abdomen in obstinate cases, and the attendants use all their force on each end. After delivery, hot bricks or sand-bags are placed on the abdomen, the body is smeared with turmeric, and the vulva plastered with saffron. On the seventh day the patient has a hot pack, and the abdomen is constantly shampooed. The results of this elaborate system of midwifery are stated to be very unsatisfactory.

The Society of Medical Officers of Health have recommended the Commissioner of Police for London to order that cabs which have been used for conveying cases to infectious hospitals should be disinfected free of expense to the cabman, who will also be provided with a certificate that his cab has been disinfected. The cushions are to be stoved, the inside of the cab washed with carbolic acid soap, the metal-work being smeared with carbolic oil, and chlorine gas evolved inside the cab, which should remain closely shut up for one hour.

A shopkeeper, who was not a chemist and druggist, was recently summoned before the magistrate at Sheffield for selling paregoric elixir which contained no opium. It appears, however, that the practice is not illegal. The law requires that all medicines of the British Pharmacopœia shall be compounded according to its formularies; but, as the term "paregoric elixir" is not mentioned as a synonyme of compound tincture of camphor in the *B. P.*, "paregoric elixir" is not a medicine under the Act, and may be made of anything. In another case the same magistrate decided that a preparation which contained any opium and any alcohol might be legally sold as tincture of opium. This decision, if maintained on appeal, would involve every prescriber in serious difficulties. Happily, it appears to be contrary not only to common sense, but also to the express provisions of two Acts of Parliament.

It is reported that a man has recently died of hydrophobia at Bolton three months after being bitten by a dog. The dog, it is said, showed no symptoms of hydrophobia, and

was in good health when killed three months after the bite. The story has been eagerly seized on by the opponents of Pasteur as discrediting the whole modern theory of the nature of rabies. So far, however, no authoritative version of the facts has been put forward, and no proof offered that the man may not have been also wounded by some other animal.

The Registrar-General reported that during the week in which Boxing-Day fell no less than thirty-five children under one year of age died in London of suffocation: this is generally interpreted to mean that they were overlaid by their mothers during drunken sleep.

Nearly every considerable town in England and Scotland is taking steps to commemorate the jubilee year of Queen Victoria, and in a large number of instances it is proposed that the movement shall take the shape of some improvement or enlargement of the existing hospital accommodations; in other instances special efforts are to be made to pay off debts. Some of the schemes, however, are meeting with a good deal of opposition: at Glasgow, for instance, where it has been proposed to erect a new hospital in the southern part of the town, it is urged that the number of beds provided is already sufficient, and that it is hopeless to attempt to raise either the sum immediately required or the annual income which would be necessary. The most portentous scheme has been broached in London: in Gloucester Terrace, Queen's Gate,—that is to say, in the very heart of fashionable London,—a hospital is to be, or perhaps has been, established for the treatment of diseases of the throat, ear, skin, eye, rectum, and various deformities of the human frame. "Only those need apply," the advertisement says, for the surgical appointments "who have had considerable experience in his respective branch." The grammar of the promoters appears to be about on a par with their estimate of the medical profession. The fact is, the Jubilee is being quite overdone: the drapers are having "Jubilee sales;" the coffee-dealers will sell you the "Jubilee blend;" the photographers will provide you with a "Jubilee portrait;" while it is the Americans, I think, who are to organize for us a Jubilee exhibition!

DAWSON WILLIAMS.

BALTIMORE.

THE rare operation of complete removal of the larynx for cancer was performed by Dr. J. H. Branham, at Bay View Hospital in this city, on January 20. The patient was a native of Switzerland, 55 years of age, and had complained of laryngeal trouble for about six months. The infiltration was located principally on the left side and posteriorly, involving the œsophagus. The latter was not discovered until the operation. A laryngoscopic examination had verified the diagnosis previously arrived at from the clinical history. The operation was demanded by several dangerous hemorrhages from the larynx, which threatened to cut short the patient's life.

The operation was done by making an incision from the hyoid bone to near the sternum, exposing the larynx and a portion of the trachea, and then separating the latter and inserting a tracheotomy-tube wrapped with cotton and gum-cloth to make a tampon of proper size to fill the trachea. The anæsthetic was then administered through the tube, through which breathing proceeded without interruption. The larynx was then dissected up and removed. The infiltration of the anterior wall of the œsophagus was so complete that the larynx could not be removed without opening up the former tube.

No vessels requiring ligation were divided. The operation lasted one hour and forty-five minutes.

The patient rallied promptly from the operation, but died thirty-six hours afterwards, of aspirating pneumonia.

The three colored men arrested on the charge of "burking," as mentioned in a previous letter, have been tried during the past week. The principal criminal, Ross, was convicted of murder in the first degree, and the other two, charged with being accessories, have been acquitted on account of lack of competent evidence to convict.

The Enoch Pratt Free Library, under the energetic administration of Dr. Lewis H. Steiner, the librarian, is adding a valuable collection of medical works to its more popular treasures. Among the more recent acquisitions are a complete set of the New Sydenham Society's publications and the official reports of the London Health Exhibition. Some of the more prominent medical journals, among them the *Philadelphia Medical Times*, are also kept on file.

Dr. Julian J. Chisolm, Professor of Eye and Ear Diseases in the University of Maryland, has been elected to the Presidency of the Section on Ophthalmology in the Ninth International Medical Congress. Dr. Chisolm is an energetic and successful ophthalmologist, widely known in his specialty both at home and abroad, and he will doubtless make his Section signally successful.

The Faculty of the Woman's Medical College have instituted a training-school for nurses in connection with the college. Lectures will be delivered eight times a week, by Drs. Browne, Winslow, Cordell, Ashby, Jay, Thomas, Taylor-Norris, and Booker.

Professor Thomas Opie has been elected to the chair of Gynæcology in the College of Physicians and Surgeons, made vacant by the death of Dr. A. F. Erich. Professor Opie also retains the deanship and the professorship of Obstetrics.

A movement is on foot, fostered especially by the Faculty of the University of Maryland, to establish a new lying-in asylum in this city. The Maryland Maternité, an excellently-managed institution, has long and satisfactorily filled a want in this direction.

At the January meetings of the Societies, Dr. Thomas B. Evans was elected President of the Baltimore Medical Association, and Dr. George H. Rohé President of the Medical and Surgical Society. G. H. R.

BALTIMORE, February 5, 1887.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA ACADEMY OF SURGERY.

AT the stated meeting of the Philadelphia Academy of Surgery held February 7, 1887, the President, Dr. D. Hayes Agnew, in the chair, Dr. Harold C. Ernst, of Boston, read a paper entitled

AN EXPERIMENTAL RESEARCH UPON RABIES.

His experiments were performed with three objects in view: first, to determine whether or not there was such a thing as a virus of rabies; secondly, if there is such a virus, does drying at an even temperature modify its strength? thirdly, does the inoculation of such modified virus afford immunity against the inoculation of a stronger virus?

The different series of experiments relating to these various points were then given in detail. The animals used in most of the experiments were rabbits, although guinea-pigs and dogs were also employed.

The following conclusions were reached:

1. That there exists in the cords and brains of animals inoculated in Pasteur's laboratory a *specific virus* capable of the production of similar symptoms through a long series of animals.

2. That these symptoms are produced with absolute certainty when the method of inoculation is by trephining the skull and injection under the dura mater; with less certainty when the inoculation is by subcutaneous injection.

3. That the strength of this virus is lessened when the cords containing it are removed from the animals and placed in a dry atmosphere at an even temperature.

4. That the symptoms produced by the inoculation of this virus only appear at a certain period of incubation, distinctly shorter when the inoculation has been done by trephining than when done by subcutaneous injection.

5. That injections of the virus modified in strength by drying, and in the manner prescribed by Pasteur, exert a very marked protective influence against an inoculation with virus of full strength.

6. That a very moderate degree of heat destroys the power of the virus entirely, whilst prolonged freezing does not injure it.

DISCUSSION.

Dr. E. O. Shakespeare: I had hoped to be permitted to be a silent listener rather than a participant in the discussion. I have been much interested in the lecture and in the way in which the subject has been presented from the stand-point of experimental work. It confirms very considerably some of the notions which I had already formed concerning this matter, from opportunities I had of looking into it while in Paris and in London, and also from some inoculating work which I have had the opportunity to do since my return. I brought home some of the virus from Paris, but I have not as yet had time to do anything but simply keep it alive. The virus which I have originated in Pasteur's laboratory. In making the inoculation necessary to keep the virus alive, I have had more or less opportunity of making some rather careless observations.

In the first place, I have been struck with the extreme regularity of the period of incubation, and also the extreme regularity of the course of the symptoms and the death after the first visible symptoms make their appearance. I have not seen such variations in the period of incubation as those mentioned by Dr. Ernst. The rabbits I obtained came directly from Professor Horsley, of Brown Institution, who is secretary of the official commission appointed by the British government to investigate the Pasteur question. These rabbits were inoculated by Professor Horsley from rabbits which he had inoculated with virus brought by himself from Pasteur's laboratory. The source of the virus is undoubtedly the same as that used by Dr. Ernst. The period of incubation in the first rabbits was about twelve or thirteen days, and the death of the animal occurred about three or four days later. The period of incubation gradually shortened, until for the last few months it has been reduced to seven days. The inoculations have been performed much in the same way as Dr. Ernst performs them. As my object has been simply to continue the virus, I have followed the more certain method of inoculating under the dura mater. Only in two instances have I made subcutaneous inoculations. When I heard ten days ago that this lecture was to be delivered, I thought for the sake of a little observation I would depart from the usual method and inoculate a couple of cats. I had understood that Dr. Ernst had failed to perceive in any of his animals what has been called furious rabies. In Professor Horsley's laboratory I have seen furious rabies both in cats and in dogs. I inoculated the cats under the skin of the back, in the usual manner, from the same cord which I used for inoculation of my last pair of rab-

bits. The rabbits died as usual, but the cats are not yet dead, and they are affected rather differently. One of the cats has the posterior paralysis, its appetite is not natural, but it does not seem to have any fits of excitability or irritation. The other cat shows no symptoms of interference with the strength of the legs, but for the last three or four days it has had a very marked excitability, and it has eaten voraciously, gulping the food down like a famished dog, and has very seldom during that period been noticed to drink anything. When water is placed in the cage it jumps towards it as if famished for drink, but as soon as its nose touches the water it recoils, but there is nothing like a convulsion. I feel that I am unable to add anything to what has been already so forcibly said from the stand-point of experimental research.

There is one point that I have noticed in my rabbits, and it has also been observed by the English Commission. I have sometimes observed, especially towards death, that the condition of the opisthotonos has its exacerbations. This condition seems to have been entirely overlooked by Pasteur. You can often see the head of the animal go up, and sometimes a tremor or twitching of the legs.

From what I have seen of the matter, and from what I have seen of the work in Pasteur's laboratory, I am strongly impressed by the practical truthfulness and justness of the claims of Pasteur not only as to the inoculability of the disease from animal to animal and from animal to man, but that it is a controllable disease by preventive inoculations. The inoculations of animals, I feel, point very strongly to that conclusion. To those who admit that there is such a thing as hydrophobia following the bite of a rabid animal, I see no serious difficulty in assuming, at least from the stand-point of analogy, that what will prevent the disease in the animal will probably prevent it in man. The inoculations which have been made in man since the first one was inaugurated by Pasteur have been very numerous, and it is quite possible that in that large number a considerable portion have been in persons who have been bitten by dogs which were not really mad, but I think, as Ernst has pointed out, the assumption is reasonable that a large number out of the three thousand inoculations which have been made have been in persons who have been bitten by animals really mad. Leaving aside all of the inoculations of those bitten by dogs, and considering exclusively the result of the inoculations of the Russians who have been bitten by mad wolves, it seems to me that this evidence added to the evidence which has already been accumulated, including that most important part offered by Dr. Ernst to-night, shows that the laws which seem to be established concerning the disease in animals apply also to man. It seems that the percentage of mortality in man after the bite of a rabid wolf is, without inoculation, about eighty-two per cent., while the percentage after inoculation has not been more than from five to seven per cent. So far as I remember, only three of the thirty-eight Russians who were inoculated have died.

This is certainly a favorable showing on the side of Pasteur. To my mind the evidence derived from preventive inoculations in man fits very rationally with the justified conclusions which are to be drawn from the experimentation on animals.

Dr. S. W. Gross: The experiments of Pasteur, so ably repeated by Dr. Ernst, show that there is a virus which when inoculated into animals produces a certain set of symptoms. The question arises whether some other form of virus may not produce essentially the same symptoms. In conversation with Dr. Shakespeare soon after his return he told me, if my memory serves me right, that after leaving Paris he went to the laboratory of Koch in Berlin, and that in walking through one of the laboratories he observed some rabbits in a peculiar position, and turning to Koch, said to him, "I see that you are making experiments on the virus of rabies." Koch replied, "No; these rabbits have been inoculated with the virus of tetanus." From what Dr. Shakespeare said, I inferred that the virus of tetanus gave rise to symptoms resembling those of rabies. I would ask Dr. Shakespeare whether or not I have reported him correctly.

Dr. E. O. Shakespeare: I distinctly remember the conversation referred to. I was much surprised, the first morning that I went to Koch's laboratory, to find a young man working with some rabbits in a moribund condition in the identical position in which rabbits usually die after the inoculation of rabies,—that is, with the head as far back as possible and the feet straight out. I remarked to Koch, "I see that you are going over Pasteur's hydrophobia work." "No," he replied; "these are animals which have been inoculated with the bacillus which has been isolated and cultivated from a case of tetanus." The symptoms with which these animals died were much the same as those of experimental rabies. There is this marked difference between the effect of the two poisons: while the period of inoculation in rabies at its shortest is not under seven days, and that is after the virus has been greatly increased in strength, the period of incubation in tetanus is not more than forty-eight hours, and the animals die twenty-four or thirty-six hours later. The earlier symptoms are not exactly like those of hydrophobia. There is a marked periodicity in the condition of opisthotonos in the animals experimented upon with the tetanus bacillus. In the intervals the animals are apparently free from spasms. This is in marked distinction to what is seen in rabies. I might refer to the

fact that within the past few months I have had the opportunity of making two autopsies in cases of tetanus dying at the Philadelphia Hospital. I was also present at the autopsy of a horse dying of tetanus at the Veterinary School of the University of Pennsylvania. I have made cultures from the cords of these cases, and I have growing something which looks like the bacillus which I saw at Berlin. It does not seem to be exactly identical with this, but I have as yet not had time to inoculate it.

I should add that in these inoculations with the virus of rabies I have been assisted by the Secretary of the Academy, Dr. J. Henry C. Simes.

(To be continued.)

OBSTETRICAL SOCIETY OF PHILADELPHIA.

THURSDAY, JANUARY 9, 1887.

(Continued from page 327.)

DR. CHARLES MEIGS WILSON reported

THREE SUCCESSFUL TAIT OPERATIONS.

These cases are the first of a series performed without the use of carbolic acid solutions for instruments and without the spray. Hydrant-water boiled for six hours was used for the instruments and sponges in the first and second cases, and a solution of mercuric chloride (one to eight thousand) for like purposes in the third. The wounds in all three were dressed after the manner of Keith. The incisions were less than two inches in length. More than three months has elapsed since the operation in each case before it has been reported. It has seemed best to publish the cases in this manner, because the vast majority of all cases recover without accident from the operation, and hence mere statistics of the healing of the wound amount to little but evidence of individual skill. Statistics of the real relief afforded by the operation is what the profession needs in order to give the operation its just place in modern surgical procedures.

Case I. Myo-Fibroma of the Uterus.—This case first came under observation in July, 1886. She gave her history as follows: Miss McM., æt. 32, nullipara. For the last sixteen months has had a rapidly-growing tumor of the abdomen, menses profuse, catamenial intervals ten to fifteen days; for the past four months has been rarely free from bloody vaginal discharge. She was emaciated and anæmic.

She was very nervous and alarmed about the constant bloody discharge. She had reflex pains, but no ovarian tenderness or pain. She was obstinately constipated, owing to the pressure of the tumor upon the rectum. She was found to have a large fibroid tumor of the fundus and anterior wall of the uterus. The enlarged uterus was incarcerated in the cavity of the pelvis, and was very immobile. The sound entered the uterus seven and one-fourth inches. Abdominal section was performed September 2, 1886, with assistance of Drs. E. Wilson, C. P. Noble, and E. Longaker. The tubes were as thick as the finger; they had thin walls, and were distended with blood. The ovaries were over size, and the right one was cystic. The ligature slipped from the uterine end of the left tube, and before it could be secured there was free hemorrhage. The operation lasted forty minutes. Convalescence was retarded by abscess of one of the suture-tracts. The patient made an excellent recovery.

Present Condition.—Has lost no blood since the second day after the operation: appetite good, and is able to resume her occupation of seamstress; frequently walks two miles to her work; all pain has disappeared; has gained twenty-two pounds since the operation. December 20, 1886, the sound entered the uterus three and one-fourth inches; the tumor was greatly reduced in size.

Case II. Hystero-Epilepsy.—Mrs. C., æt. 30, primipara. Had always enjoyed good health until after the birth of her child six years ago. She had been delivered with forceps, and the cervix and perineum had been badly torn. She was in bed nine weeks after the confinement. No clear history of her puerperal trouble could be obtained. She has had profound catamenial discharges since. About six months after the birth of her child, she first commenced to have attacks of loss of consciousness followed by epileptiform seizures at her menstrual periods. These gradually became so violent as to place her life in seeming jeopardy during their occurrence, and left her utterly prostrated. She had been in bed about twenty days out of every month for four years. Her epileptic seizures occurred only at her menstrual periods. Everything that her medical attendant could think of had been done for her, and her family were about to place her in an insane asylum. The ovaries and tubes were removed October 3, 1886. The operation was an easy and simple one. The patient made a speedy recovery without any untoward symptoms.

Present Condition.—She is now able to earn her living as a yarn-picker, working full time; has had no discharge of blood; little or no pain; *and not one seizure since the day of operation.*

Case III. Tubercular Pyosalpinx.—Miss E. R., æt. 19, nullipara. This patient was also operated upon on October 3, 1886. Since menstruation began, at fifteen years of age, she has had constant dull, aching pain, deep-seated in the pelvis. At her menstrual epochs "her agony has been unbearable." The menses have always been slight in quantity and regular as to time. She presented a badly-

nourished appearance. Physical examination showed marked evidence of general tuberculosis. In spite of this fact, and in view of her intense menstrual pain, oöphorectomy was deemed justifiable, and was accordingly done. Both tubes were as large as large bologna sausages, and both ovaries were cystic. Tubes and ovaries were matted in a mass of adhesions, which rendered the operation very tedious, it lasting one hour and ten minutes. Microscopic examination of sections of the tubes showed colonies of the bacillus tuberculosis. Both tubes were filled with a greenish pus, which was very offensive. The recovery was complicated by an arthritis, the symptoms of which were so obscure as to render it difficult to say whether it was septic, rheumatoid, or hysterical. She eventually made a good recovery.

Present Condition.—Her physician, Dr. Walter E. Bibby, of Kensington, Philadelphia, reports, "She is entirely free from pain, able to walk about and to attend to light household duties. Under the use of cod-liver oil and malt and alcohol, her tubercular trouble seems to be making little or no progress." As her peritoneum showed evidence of tuberculosis, as an experiment, bichloride solution, one to eight thousand, was used to wash out the abdominal cavity.

Cases II. and III. were operated upon before Drs. A. W. Biddle, W. E. Bibby, W. C. Goodell, E. Wilson, E. Longaker, and C. P. Noble. All were done at the Philadelphia Lying-in Hospital. In each case the abdominal cavity was thoroughly flooded with boiled water before it was closed. The drainage-tube was not used. The carbolized Chinese-silk ligatures and silkworm-gut sutures were used. No anodyne was given, and no food was given for thirty-six hours after operation.

Dr. H. A. KELLY was particularly interested in the tuberculous tubes, and regretted that an examination of the uterine discharges had not been made, as it would almost certainly have established the diagnosis. As to the right to operate upon a patient having a cavity in the lung, no general rule can be laid down; every such case stands by itself, and much must be left to the judgment of the operator.

Dr. BAER would hesitate for some time before operating in a case of general tuberculosis with a pulmonary cavity. He did not think tuberculosis could cause pyosalpingitis.

Dr. KELLY remarked that at least two cases have been observed here, and many more abroad, and it has been recently formulated by Professor Hegar among the tubal diseases which may require operation.

Dr. PARISH thinks the general condition of the patient outside of the pulmonary disease would decide the question. Severe pain should be relieved unless the patient had a very short time to live.

HYDROSALPINX.

Dr. H. A. KELLY exhibited the tubes of a patient who had suffered from metrorrhagia over thirteen years. She had been in five large hospitals in Philadelphia without relief, and had faithfully tried every plan of treatment, systemic and per vaginam. The diagnosis of enlarged tubes was made before operation, and on removal with their respective ovaries the tubes were found one as large as a bologna sausage and the other a small sausage, with a limpid fluid. She has lost no blood since the metrostaxis following the operation about six weeks ago.

Dr. KELLY also exhibited fresh large cystic ovaries and tubes of a large fibro-cystic tumor, upon which he had operated in the morning. The ovaries were sessile, surrounded by congeries of great dilated vessels. The operation was one of extreme difficulty. (Note, five days after operation: "The patient's condition is perfect.")

The patient whose history was read at the preceding meeting, who had ovaries and tubes removed for chronic subinvolution and endometritis, was presented to the meeting. She has lost all pain, and feels perfectly well for the first time in years. The uterus is normal.

Dr. PARISH reported a Porro-Müller operation.

W. H. H. GITHENS,
Secretary.

JOINT MEETING OF THE PHILADELPHIA NEUROLOGICAL SOCIETY AND PHILADELPHIA MEDICAL JURISPRUDENCE SOCIETY.

A JOINT MEETING of these Societies was held at the Hall of the College of Physicians, January 24, 1887. The meeting was also the stated meeting of the Philadelphia Neurological Society. The President of the Neurological Society, Dr. S. WEIR MITCHELL, presided.

Dr. E. N. BRUSH read a paper on

THE DUTY OF THE STATE TO THE INSANE.*

DISCUSSION.

Dr. S. WEIR MITCHELL: With reference to the question of joint examinations, I think that the law does not forbid such examinations. It only makes necessary a separate examination by each physician. The joint examination, with all the good that arises from it, may follow. I favor separate examinations. Then the physician makes the whole examination for himself, while in the joint examination there is apt to be too much reliance put upon the opinion of the man older in the case.

Dr. M. O'HARA: It appears to me that the present certificate is a very poor one. It de-

* This communication will appear in the next issue of the *Times*.

bars many from making the examination who should have a right to do so. Any one connected in the most remote degree with an institution cannot sign the certificate. Many physicians cannot be induced to go on a certificate. They are not willing to undertake the risks of subsequent prosecutions for false imprisonment of the patient. There follows, as a necessary consequence, that the practitioners who are probably most conversant with the case—for instance, family physicians —refuse, and thus the patient is handed over to strangers who are willing to take chances. Thus an early care of the insane tending to cure is prevented by the State not protecting medical men who are acting conscientiously in the line of their duty and with their highest judgment. The State should protect a physician, or otherwise give over the whole matter to a judge and jury.

Dr. T. S. SCHULTZ: I should like to emphasize the point in this admirable paper which refers to the present lack of accommodations for those who are not paupers and yet are not in circumstances to pay the rates charged by private hospitals. The law requires that the State hospitals receive public patients to the exclusion of those who can support themselves when there is not room for all applicants. There are many patients whose friends can pay the moderate sum which is charged by the State hospitals, but not any more. So long as these friends refuse to be pauperized by throwing their small means into the poor-treasury, they cannot secure any accommodation. And this their self-respect, which is most commendable, prevents them from doing.

It is, to say the least, unfortunate that such persons, who are often curable, should be crowded out of State institutions, which they assist to support by their taxes, by idiots, imbeciles, and chronic and criminal insane, all beyond the reach of curative treatment.

Dr. H. C. WOOD: I feel to-night like saying a few words in regard to the protection of a class of the community in which I have a personal interest, and among which I long hope to dwell: that is, the protection of the sane. This subject has been forcibly brought to my attention during the past week. While at an insane asylum, visiting a patient, the conversation turned on our lunacy laws, and the gentleman in charge stated that not long ago he had a patient liberated by the Committee on Lunacy who went home, and was at once adjudged insane, and incarcerated in an asylum in another State. I happened to go from there to the house of a patient in this city, and found the family considerably excited. They told me that a friend who had been in an insane asylum for a number of years, whose brother had killed a man and had been acquitted on the ground of insanity, had been liberated by the Committee on Lunacy. Shortly after this I met a physician in consultation, and he told me that not long ago he had sent a patient to the insane asylum, and that he had been liberated by the Committee on Lunacy. The patient then came to his office and told the doctor that he had no grievance against him for sending him to an asylum, but that he had a divine monitor in his breast which told him that the doctor was wrong in the judgment of his case. I do not mention these facts to find fault with the Committee on Lunacy. It is far from my desire to leave such an impression. These occurrences seem to me to indicate some vital defect in the law under which that Committee acts. As I understand it, there is no one on the Committee of Lunacy who would be recognized as an alienist. The law should require some one having experience in this disease to be on the Committee.

Again, I have over and over had my attention brought to cases of dangerous lunatics at large in the community, from whom it seemed impossible to have the community protected. A year and a half ago I was consulted in regard to a gentleman who had attempted first to seduce, and, this failing, to rape, his own daughter, and was only prevented by her outcries being heard outside of the house and bringing assistance. I said that the man was undoubtedly suffering with general paresis, and told the physician in charge that it was his duty to do something to protect the community. The family refused to have the man restrained. The attempt on the daughter was followed by an attempt on a stranger, which also fortunately failed. Yet the man was permitted to be at large for months after this occurrence.

I have been present at a number of trials in which the defence was insanity, and I have never yet seen a case in which the plea of insanity was fairly justified in which it was not equally plain that the man, before the commission of the offence, clearly portrayed that he was a dangerous lunatic. It seems to me that the law should provide that some one having authority should take hold of these cases.

THOMAS W. BARLOW, Esq.: I wish to make a few remarks with reference to the accountability of physicians who sign certificates of insanity. The passage of such a law as would lessen such accountability would, in my opinion, be repugnant to the progress and spirit of the age, the progressive and humane spirit which in this State pervades the laws thrown around those deprived of their reason. For many years laws have been enacted which more closely protect the liberty of the people. In New York State, wives have been permitted to testify where their husbands have been accused of crime. In this State, recently, persons accused of any grade of crime have been permitted to testify for themselves. This has been the spirit

which has pervaded all laws passed within recent years. Now, in my opinion, sir, not only should the physicians be held accountable for what they do, not only should two physicians separately examine the patient who is supposed to be of unsound mind, but if it were possible to throw around such persons a greater protection, I should favor any such enactment.

In reference to the remarks of the gentleman who has just taken his seat, I would ask whether he himself knows or does not know if the woman who was recently released from an insane asylum, and whose brother was acquitted on the ground of insanity, is now a sane or an insane woman? This is the gist of the subject. He gives no instance of her present insanity; he has made no examination of her mental condition. He does not give us the weight of his authority, which is a most excellent one. It seems to me that, for his reasoning to have any weight, we should also have the weight of his opinion. In one instance in which the gentleman was an expert for the defence in the case of a man on trial for murder, the prisoner, four days prior to his execution, threw off the mask and admitted that he had been playing upon the imagination or credulity of his friends and physicians.

Dr. H. C. Wood: I did not give the weight of my opinion in reference to the cases to which I have referred. They were simply things which had called my attention to this subject. I do say that, so far as I know, there is no way, according to the laws of Pennsylvania, to protect the community from a dangerous lunatic if his friends decline to interfere. I have seen numerous cases, one of which I cited, in which criminal assaults were at all times imminent. In regard to the case to which the last speaker has referred, we have often discussed it. The evening is short and the papers are many, and I do not propose to be drawn into a discussion of it tonight. I followed that man nearly to the gallows, and I saw no reason to modify my opinion. In the last days of his life he was in that mental condition in which, under skilful leading questioning, he could be induced to assent to almost any proposition that was made to him.

(To be continued.)

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held January 26, 1887, the President, T. Mitchell Prudden, M.D., in the chair.

DOUBLE MITRAL ORIFICE.

Dr. W. H. Porter presented a heart with a double mitral orifice, the accessory one being smaller than the other. He knew of no similar case.

SYMPTOMS OF FRACTURE AT THE BASE OF THE SKULL.

Dr. Porter said that the case from which the specimen just referred to was obtained was further interesting from the fact that the man had been transferred to Bellevue Hospital, where the diagnosis of fracture of the base of the skull was made, based on the presence of a peculiar serous and hemorrhagic discharge from both ears and bruises upon the face pointing to injury. Death took place a few hours after he entered the hospital, and post-mortem examination failed to reveal any fracture of the skull.

INTERNAL URETHROTOMY USELESS.

Dr. Porter further said that the patient was found to have had a urethral stricture about four inches in length, involving the membranous and bulbo-membranous portion. It illustrated very well the reason for not dividing these strictures by internal urethrotomy, inasmuch as in that operation it was the custom to cut the roof of the urethra, whereas the stricture in this case and in other cases which he had examined was confined to the floor of the urethra.

MILIARY ANEURISM OF THE BRAIN.

Dr. Porter also demonstrated a miliary aneurism of the cortical substance of the brain, it being the clearest example of that lesion which he had yet obtained. The aneurismal dilatation was globular; the proximal part of the vessel next the aneurism was somewhat enlarged and the distal part somewhat narrowed. All the vessels of the body had thickened walls. There were no larger aneurisms.

LEPTOMENINGITIS AND PACHYMENINGITIS.

Dr. L. E. Holt presented the brain of a child, aged 20 months, showing distinctly the lesions of leptomeningitis and of pachymeningitis. It was interesting chiefly in connection with the history, the patient, although weakly and having an irregular temperature a considerable time, not presenting the symptoms of meningitis. Tuberculosis had been suspected, as a twin and the mother had died of that disease, but physical examination had failed to reveal any signs of tubercles. Three or four days before death the temperature steadily and rapidly increased to 105.5°, and a few hours before death to 108°, and there was evidence of meningitis. The leptomeningitis was evidently recent, the pachymeningitis of weeks' or months' duration.

SALPINGITIS.

Dr. Pryor presented, by the courtesy of Dr. Sims, the fundus of the uterus to which was attached a tumor formed by pyosalpinx. The symptoms had been those ordinarily accompanying so-called recurring cellulitis. At

the operation the tumor was found attached to the uterus in such a manner that it was necessary to remove with it the fundus of that organ. The woman died nearly three days later from stricture of the bowel by an old adhesive band. The specimen was interesting from the fact that the tumor contained a number of pus-cavities, the larger of which were supposed to occupy the place of the canal.

Dr. PRUDDEN said he had examined the specimen carefully for bacteria, and he had failed to find any bacteria of suppuration in the pus.

STRICTURE OF THE ŒSOPHAGUS FROM MALIGNANT DISEASE.

Dr. ROOSEVELT presented the œsophagus and stomach of a woman who had suffered from vomiting and pain in the region of the stomach. About six months before death she was first seen by him, and soon afterwards the pain entirely ceased, but she continued to vomit a short time after eating. She was able to take a quart of fluid at a time; and after retaining it for a while it would return without special expulsive effort, and without apparent change. He supposed she was suffering from chronic gastritis, but discovered, on trying to introduce a tube to wash out the stomach, that there was a stricture near the cardiac orifice through which he was able to pass at autopsy a probe only of medium size. The autopsy also revealed dilatation of the œsophagus up to about the level of the thyroid cartilage to nearly the size of a quart champagne-bottle. The stomach was narrowed. The stricture existed near the cardiac orifice, and was due to small nodules surrounding the œsophagus, malignant in nature. One point of interest in the case was absence of pain the last six months of life.

Dr. I. T. VAN GIESON presented a variety of tumors found in different organs of a dog.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, JANUARY 24, 1887.

The President, LAURENCE JOHNSON, M.D., in the chair.

THE USE OF ACONITIA IN THE TREATMENT OF NERVOUS DISEASES.

DR. WAITZFELDER read the paper, first giving the origin of aconitia, a description of the crystalline and amorphous forms, and their physiological action. It appeared that the action of the drug on the nervous centres was, first, that of irritation, and, afterwards, that of paralysis.

As to its use in the treatment of diseases of the nervous system, it was in neuralgias that it is of special service. The experience of authorities in the diseases of the nervous system was first given; afterwards his own experience was related. Dr. Waitzfelder had succeeded in curing some and in relieving others who had suffered from facial neuralgia for a varying length of time. He thought that here its use should be persisted in until it was proved to be without utility, before an operation was determined upon. He had found a combination of aconitia and veratria to act better than aconitia alone for external use. Precaution should be taken in using it over the eye, cuts, or bruises, to avoid constitutional poisoning. It had proved of benefit in two out of three cases of chronic sciatica in which he had employed it. In the treatment of pachymeningitis, whether specific or not, it had occasionally been of benefit. A marked instance was cited, the neuralgic pains being of syphilitic origin, and specific treatment had failed. There was almost always some success in such cases, though not effected so quickly, within three days. He thought it ought to be of service in multiple neuritis from toxic causes, although he had not had experience in this direction. It was of benefit in active congestion of the brain from excessive action of the heart; combined with bromide of potassium, the two drugs shortened the period of excitement and hastened cure. He thought the more important effect was from the aconitia. It was also of use when combined with small doses of bromide of potassium in certain cases of insomnia from business-trouble, etc. Patients with exophthalmic goitre had expressed themselves as feeling better after its use, although it had had no appreciable effect upon the tumor or eyes. It was of use in certain cases of spinal irritation with hyperæsthesia.

Dr. DAVID WEBSTER had found aconitia beneficial in a few cases of nervous affections in which he had seen it employed.

Dr. LESZYNSKY pointed out certain precautions in its use, particularly in conditions where there was a tendency to exhaustion or depressed general health. He had given up its use in sciatica. It was certainly of value in pachymeningitis.

Dr. MESSENGER had also largely given up the drug because of its power and the consequent danger attending its use.

THE RELATIONS OF THE MEDICAL PROFESSION TO THE HEALTH DEPARTMENT.

The paper was written by Dr. JOHN C. PETERS, and in his absence was read by the Secretary, Dr. CARPENTER. It was an arraignment of the Board of Health for dereliction of duty in failing to abate certain nuisances, and charged it with being under the influence of politicians. He thought the President of the Board should be a physician, which the law does not at present permit.

A report from the Committee on Hygiene was read regarding the baling of manure.

Objections to the method had been offered, particularly because the manure was thus spoiled for enriching ground from having lost its ammonia and become "fire-fanged." The following motion was passed:

"*Resolved*, That the Medical Society of the County of New York earnestly requests the Board of Health to abate the nuisance of removal of the manure as it is done at the present time in the city; and until this question is settled it is requested to see that the manure is removed, as other offal is removed, between twelve and three o'clock at night."

The opinion of Justice Sedgwick in the case of Brown *vs.* Purdy, not sustaining the opinion of the lower court, was read by the Secretary.

MISCELLANY.

PHILADELPHIA CLINICAL SOCIETY.—At a stated meeting of the Philadelphia Clinical Society, held January 28, 1887, the following officers were elected:

President.—Dr. James B. Walker.

First Vice-President.—Dr. Mary E. Allen.

Second Vice-President.—Dr. Susan P. Stackhouse.

Treasurer.—Dr. L. Brewer Hall.

Recording Secretary.—Dr. I. G. Heilman.

Corresponding Secretary.—Dr. Emma Musson.

Reporting Secretary.—Dr. Mary Willits.

Counsellors.—Drs. Edward R. Stone, Edward E. Montgomery, Amy S. Barton, A. Victoria Scott, Hannah Y. Croasdale.

NOTES AND QUERIES.

CRUDE PETROLEUM AS AN ANTISEPTIC DRESSING.

Having been in active practice for about twenty-five years in the woods, where accidents are frequent and the resources for dressings limited, I wish to give the results of my experience in treating gunshot-wounds, resections, compound fractures, injections in abscesses, extensive sloughing, snake-bites, and burns, with petroleum. I use the pure heavy oil from the wells of West Virginia. In exploring a wound I use it on the probe or finger. After cleaning the wound, I then pour the wound full and keep it so until it is entirely healed. I will briefly refer to a few cases.

Case I.—P. M., gunshot-wound of upper thigh: poured wound full, after being tamponed on under side; kept it full of oil until it entirely healed, and without a drop of pus.

Case II.—Mrs. S., resection of os calcis: kept wound well saturated with oil; it healed without an unkind symptom.

Case III.—O. D., terribly lacerated hand from gun bursting: kept hand well swathed, using a gallon of the oil, with the very best result.

Case IV.—G. A., legs crushed in saw-mill, compound fracture, with resection: dressed as above; very little suppuration and perfect repair.

I could cite many similar cases. In a lacerated or sloughing wound, it being heavier than the serum and pus, it penetrates every part of the wound and floats them out. In a slicing wound I use white wool yarn (which is slightly elastic) dipped in the oil, and wind the slice perfectly in place, leave it on a week, and find union with no scar. Since using petroleum I have never had a case of erysipelas or septic poisoning from a wound of any description, and as a local application for inflamed surfaces or herpetic eruptions it is the best I have found. The only objections are the slightly unpleasant odor and staining of the linen. But it is clean, grateful to the patient, and perfectly antiseptic. I would recommend for it a fair trial by the profession.

WILLIAM P. MCKIBBIN, M.D.
BUCK VALLEY, FULTON COUNTY, PENNSYLVANIA.

AN EASY WAY OF PERFORMING TRACHEOTOMY.

One of the great drawbacks to performing tracheotomy in cases of diphtheria and croup requiring such relief is the natural timidity and want of self-confidence in the general practitioner, unaccustomed to the employment of surgical measures, and who has a natural shrinking from the use of the knife. All physicians of large experience remember cases in their own practice that might have been saved by operative interference; in country practice more especially, where the family doctor cannot conveniently employ a surgeon, and, recognizing his own inability to operate, the patient has died for want of such assistance.

Now, I propose a way of operating that any doctor of ordinary judgment can do with ease and safety. I do not know whether the idea is original, but I have never seen it in print, and have only discussed it with one or two physicians. The instrument is a curved trocar and canula of large size. Its insertion between the rings of the trachea is readily accomplished, a moment is sufficient, there is no hemorrhage, and when the trocar is removed the canula serves as a tracheotomy-tube already in position. The ordinary instrument will do, but any instrument-maker can make such improvement and alteration as the individual operator may direct.

COMEGYS PAUL.
BELVIDERE, NEW JERSEY.

[It does not appear that our correspondent has yet had an opportunity of carrying out this expedient, which theoretically is simple, but in practice would not always be easy. Where there is much œdema of the neck, or much adipose, great difficulty would probably be experienced in striking the trachea with the trocar or in avoiding transfixing it. Where the neck is thin and the trachea almost subcutaneous, this method might be worth keeping in mind in cases of threatened suffocation. In any case, preliminary incision of the skin would be advisable, on account of the resistance offered by it to the point of the trocar, and after the trachea is exposed most surgeons would prefer dividing the rings with the bistoury. Intubation would in most cases probably obviate the necessity of tracheotomy by any method.—ED.]

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM JANUARY 30, 1887, *TO FEBRUARY* 12, 1887.

MAJOR BLENCOWE E. FRYER, SURGEON.—Ordered to Fort Lowell, Arizona Territory. S. O. 29, A. G. O., February 4, 1887.

CAPTAIN L. Y. LORING, ASSISTANT-SURGEON.—Leave of absence still further extended three months, on surgeon's certificate of disability. S. O. 29, A. G. O., February 4, 1887.

CAPTAIN LOUIS BRUHENSIN, ASSISTANT-SURGEON.—Granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be spared by his department commander. S. O. 28, A. G. O., February 3, 1887.

CAPTAIN JUNIUS L. POWELL, ASSISTANT-SURGEON.—Granted leave of absence for two months, to take effect when his services can be spared by his department commander. S. O. 24, A. G. O., January 29, 1887.

FIRST-LIEUTENANT C. C. BARROWS, ASSISTANT-SURGEON.—Ordered for temporary duty as post-surgeon at Fort Barrancas, Florida, to take effect upon the expiration of his present leave of absence. S. O. 24, Division of the Atlantic, February 3, 1887.

FIRST-LIEUTENANT JOHN L. PHILLIPS, ASSISTANT-SURGEON.—Leave of absence further extended one month. S. O. 29, A. G. O., February 4, 1887.

FIRST-LIEUTENANT H. S. T. HARRIS, ASSISTANT-SURGEON.—Ordered from Fort Clark, Texas, to Fort Ringgold, Texas. S. O. 16, Department of Texas, January 31, 1887.

FIRST-LIEUTENANT LEONARD WOOD, ASSISTANT-SURGEON.—Ordered to proceed to these Headquarters, and report to the department commander for temporary duty. S. O. 12, Department of Arizona, January 31, 1887.

FIRST-LIEUTENANT PAUL CLENDENIN, ASSISTANT-SURGEON.—Ordered for duty as post-surgeon at Camp Pena Colorado, Texas. S. O. 14, Department of Texas, January 26, 1887.

PHILADELPHIA MEDICAL TIMES.

PHILADELPHIA, MARCH 5, 1887.

COLLEGE OF SURGEONS LIBRARY

ORIGINAL LECTURES.

ON ELECTROLYSIS IN THE TREATMENT OF STRICTURE OF THE URETHRA.

Delivered, by invitation, at the Medico-Chirurgical College of Philadelphia, February 5, 1887,

BY ROBERT NEWMAN, M.D.,
New York.

WHILE electrolysis is an established fact, explained in every text-book on chemistry and made use of in commercial circles and even by mechanics, it has taken the medical profession, at least in some quarters, a long time to recognize its importance in surgery.

The term *electrolysis* is defined as the process of decomposing a compound body by electricity. Applied to strictures, the action is "a galvanic, chemical absorption." *Absorption* is the process or act of passively disappearing into some other substance through molecular or other invisible means; *e.g.*, the absorption of light, heat, or electricity. Pathological products may be made to disappear in this manner. Electrolysis of light currents will induce absorption, while in strong currents it will destroy tissues. For the treatment of urethral strictures we depend, therefore, on the physiologico-chemical decomposition of the morbid products by electrolysis which absorbs and does not destroy tissue. I will first direct your attention to the exhibition of instruments necessary for the operation.

Any good *galvanic* battery of twenty cells can be used for electrolysis. The expert and specialist may have large instruments with auxiliaries, but the general practitioner can begin by using a small battery, which suffices for most of the operations. The Bunsen elements of zinc and carbon have given the best satisfaction, with cells made of hard rubber containing a solution of dilute sulphuric acid and bichromate of potassium. The fluid ought not to be too strong, or the action will be very violent at first, and the polarization too rapid, very soon weakening the current and incrusting the elements with crystals. The battery must be arranged for intensity rather than quantity. Practically speaking, the current must not cauterize the surface, or cut and destroy tissue like the galvano-cautery, but must work in the manner already indicated. The main point is to use the constant current of the galvanic battery, and not an interrupted current of a faradic or electro-magnetic machine. The difference can be seen here by the two different instruments made by Flemming, of this city. I have also brought with me an old instrument, which I used many years ago, made for me by the late A. Chester. It is so simple that its construction can be seen at once. To this battery are attached the conducting wires.

In order to use electrolysis intelligently, it is of the greatest importance to know the difference and peculiar action of the two poles. If we decompose water by electricity, we find that the oxygen is attracted by the positive, and the hydrogen by the negative, pole. Now, we should remember that *pure* water is not easily decomposed, but the difficulty is overcome if the water holds some salts in solution. If so, then the positive pole will attract the acids, and the negative the alkalies and bases. Hence it is that the positive pole acts like an acid and burns like fire; not only is this exceedingly painful, but it may leave a hard resilient cicatrix. On the other hand, the negative pole acts more like a caustic alkali, which does not hurt so severely during the application, and leaves, if carried to excess, a cicatrix which is soft and not retractile. Having become acquainted with the different properties of the poles, which possess each their own specific powers, it is evident from the foregoing that for the immediate destruction of tumors and strictures the negative pole should be selected. Therefore the principal actions of the poles in electrolysis will be as follows:

Positive pole coagulates the blood, and attracts acids and oxygen.

Negative pole dissolves the blood, attracts alkalies, bases, and hydrogen, coagulates albumen, and produces absorption.

To illustrate the action of the poles as described, I will now electrolyze a solution of iodide of potassium in water. This can be done by simply holding both poles in the solution while the galvanic battery is generating electricity.

The experiment, however, which I now will make before you is more strikingly

demonstrative, and I believe is original with me. These two small glass vials I fill with a solution of iodide of potassium. The bottoms of the vials are substituted by a piece of a pig's bladder, the necks of the vials are then stopped by a cork, through which runs a platinum wire, one end of which is immersed in the solution, and the other end from each bottle is attached to one pole of the galvanic battery.

Both vials, so closed, are now placed in a dish of water; they are six inches distant from each other. There is, as is seen, no communication between them except the water, and so long as the battery is at zero you will see no change in the solution, which is transparent and undisturbed. Please notice the change which now takes place as soon as the battery begins to act. I begin with only six cells, and you will notice almost immediately in the vial connected with the positive pole that in the clear solution streaks of yellow appear, and in about five minutes the vial contains only a dark-yellow fluid, which is the iodine set free at this pole. At the negative pole the contents of the vial remain clear, only the bubbles of froth welling up. This is the hydrogen set free from the water. The result of this electrolysis is iodine, oxygen, and hydriodic acid at the positive pole, while at the negative pole we find hydrogen and potassium.

If this same experiment be tried with a faradic battery, as I have often verified, no change whatever takes place in the solution. This is another proof that the action of the galvanic current is widely different from that of the faradic, and that for electrolysis a galvanic current only can be used.

Now, let us make another experiment to demonstrate the action of electrolysis with a stronger current, which will destroy tissues. Into a piece of raw meat we insert, at an interval, two platinum needles, each of which is connected with one pole of the battery. The action of each pole can now be distinctly observed, and we recognize the action of the negative pole by its white bubbles, which form a large surface of white froth around the needle, while at the positive pole we find a black, charred surface, indicative of the destruction like that caused by a concentrated vegetable acid.

The battery should never be used for an operation before it has been ascertained to be in good working order. There are several ways of doing this after the elements have been immersed into the fluid.

1. By taking one pole in the hand and touching the other on the tongue. This is disagreeable, and may hurt the operator.

2. By holding the poles on the hand, which also is unpleasant.

3. By touching the carbons or metals of the two poles against each other, when a spark will be seen. This is good, but must be done with care, as a too long contact of the pole will polarize the battery.

4. By the use of a galvanoscope. If the poles are touched, the needle will move towards the positive pole.

5. In the same manner, with a galvanometer or ampèremeter.

6. If the two poles are held in water the bubbles around the one pole will show that the battery is in order, and that this is the negative pole attracting hydrogen.

7 and 8. The former experiments with meat, or the decomposition of a salt.

We now come to the method of application.

The short, curved electrode which I show you here is a perfect instrument, smoothly polished, without any inequalities, and well insulated except at its extremities. The terminal is silver-plated, an egg-shaped bulb of metal, to be used at the seat of the stricture. The set goes from No. 11 (French) up to No. 30. The other set is made in the same manner, but straight, six inches long, and at the end a bulb of an acorn-shape. This form is used for the first five or six inches of the urethra, and particularly for strictures near the meatus. In very tortuous strictures, when it is difficult to find the course of the urethra, I use tunnelled electrodes over a guide or a filiform bougie.

I next show you a milliampèremeter, which is used to measure current-force of the electricity. As these instruments are comparatively cheap (can be bought from ten to thirty-five dollars), it is well that every operator should possess one. I have been wrongly accused of neglecting to express the electricity by measures, and only stating how many cells were used. I have used the number of cells only that it should be understood by everybody, but I always recommend a true measurement. An ampère is equivalent to the strength furnished by an electro-motive force of one volt passing through a resistance equal to one ohm. The cells of my battery give a tension of

half a milliampère. Therefore if I state I have used eight cells, it means generally four milliampères. This calculation varies somewhat according to other influences, but particularly according to the internal and external resistance. Good instruments which measure exactly, without fail, are too costly to be used ordinarily by the practitioner of medicine.

The *modus operandi* is usually as follows. After the patient's history has been taken, the topography of the urethra should be well ascertained and the strictures measured,—how small they are, how many, and the distance from the meatus at which they are located.

The exploring instrument transmits to the fingers certain sensations, which experience soon classifies, and which culminate in a high tactile expertness. I use for the purpose a whalebone *bougie à boule*, which has a small olive-shaped head and slender neck; this adds to its flexibility. Such an exploring instrument gives, from its peculiar shape, a delicacy of touch not to be obtained by any other known bougie. It defines with scientific exactness the nature of the stricture; the progress of altered tissue can be ascertained and defined by it with a comparatively small experience and with great certainty.

Assuming that the diagnosis has been made and the preceding means employed in order to ascertain the condition of the stricture, certain sensations will be revealed by touch; and in order better to comprehend this I may compare them with some well-known material, such as a feeling of velvet or velveteen, of paper, of parchment, or of cartilage.

In the normal state of the urethra the bougie glides with comparative ease over its moist mucous lining. The skilled finger will readily detect any alteration or deviation, its relative and comparative severity, and the slightest encroachment on its normal standard will be revealed. The velvet touch represents a slight alteration only.

For ocular inspection of the urethra I have always used the endoscope, when necessary.

The patient's susceptibility to the galvanic current is to be learned by applying it to his hand or some other part of his body. The posture which the patient should assume during the operation is a matter of slight importance: according to his convenience, he may stand, sit, or lie on his back with his shoulders elevated and his knees drawn up. Anæsthetics are not used, because no pain should be caused, and because the patient ought to be conscious, so that he can express his sensations. For ordinary strictures, the size of the bougie selected should be three numbers (French) larger than the stricture.

The fluid of the battery should not be made too strong.

The elements of the battery are immersed in the fluid, the slide standing at zero.

The electrode is well greased with glycerine, which is a good conductor.

Having ascertained by actual measurement the locality of the stricture or strictures (if there be more than one), I push a small india-rubber ring over the bougie for each of them. This little manœuvre has many advantages: not the least important is that I am made aware as soon as the india-rubber ring arrives at the meatus that the extremity of the bulb must be in contact with the stricture.

Having the plan of the urethra from actual measurement before me, I operate with additional certainty, and beyond a peradventure as to the part which is acted upon.

This bougie electrode is then introduced into the urethra until the bulb is arrested by the stricture. A sponge electrode, wet with warm water and connected with the positive pole of the battery, is then held firmly against the patient's skin (best in the palm of the hand or pressed against the abdomen, the thigh, or some other part), to complete the circuit. While both poles are held in this manner, the current is to be increased very slowly and gradually, one cell at a time, until the patient feels a warm and slightly pricking sensation. The operator should keep the bougie steadily against the stricture, and he will soon find absorption taking place, the stricture yielding, dilating, and the instrument slowly advancing and passing the obstruction: at times it fairly jumps through the stricture. If there are more strictures than one, the bougie should be guided in the same way until it enters the bladder. Then the electrode is to be withdrawn slowly, and each stricture well worked out until the first stricture is passed, when the current is again to be reduced slowly, cell by cell, to zero; and not until then is the electrode to be removed. During the whole operation the electrode must be held

loosely and gently in its place against the obstruction, all pressure or force being avoided. The bougie will take care of itself, doing its work by the electrolytic action of the current. A *séance* might last from five to twenty minutes.

The observance of the following rules would conduce to success:

1. Begin the use of electrolysis carefully, not cauterizing, but only causing absorption, six cells being enough in many cases, or a current-strength of two and a half to five milliampères.

2. Regulate the current according to the susceptibility of the patient.

3. Repeat the *séances* at intervals of three or even four weeks, the shorter intervals being exceptional.

4. Do not lubricate the electrode with a non-conducting substance.

5. Wet the sponge electrode with hot water.

6. Keep the plates in the battery-fluid only during the operation.

7. Never use force with the bougie; never cause hemorrhage.

8. Do not operate while the urethra is in a state of acute or subacute inflammation, or when the application causes pain.

9. Do not use the battery-fluid too strong.

10. Never use two bougie electrodes in succession at one *séance*, or follow the bougie with any other instrument.

11. Do not push the bougie to and fro in the urethra; it must be passed only once down and back again, and that with care.

In conclusion, I will merely say that all urethral strictures are amenable to this treatment by electrolysis, but the great advantages of this treatment I cannot discuss, as the hour has expired.

68 West Thirty-Fifth Street, New York.

ORIGINAL COMMUNICATIONS.

DESCRIPTION OF THE BRAIN OF JOHN M. WILSON, RECENTLY HANGED AT NORRISTOWN.

Read before the Philadelphia Neurological Society

BY FRANCIS X. DERCUM, M.D.,

Pathologist to the State Hospital for the Insane at Norristown; Instructor in Nervous Diseases in the University of Pennsylvania.

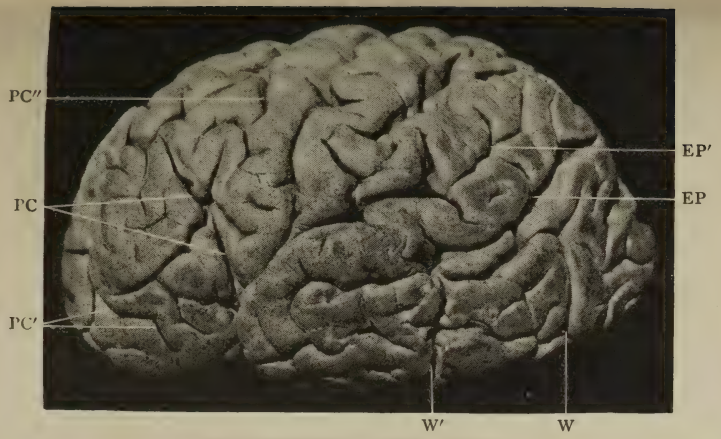
THE brain came into the possession of the writer accompanied by a portion of the dura mater and the other enveloping membranes. Drs. R. H. Chase and Henry Sykes made a verbal report to me in reference to the skull. In the first place, the head was unusually large, while the face was disproportionately small. On opening the cranium, over six ounces of cerebro-spinal fluid escaped. The bones were very thin, and the sutures all completely fused. The dura was thickened and decidedly adherent to the inner surface of the calvarium, thus giving evidence of external ossific pachymeningitis. The pia was thickened, loose, and excessively œdematous. Its meshes were everywhere filled with fluid. In addition, it was injected and presented numerous milky opacities, such as are not infrequently found in alcoholic subjects. On the mesial surfaces of the hemispheres the two opposed layers of the pia, where not separated by the falx, were everywhere coherent, thus showing positive inflammatory change.

The two hemispheres were unequal in size, the left being much the larger. The lateral ventricles were somewhat dilated, and their walls excessively pale, as were also the walls of the third ventricle. The white substance of the brain, too, was likewise unusually pale, though here and there some of the smaller vessels appeared injected, probably due to the mode of death. The velum interpositum was infiltrated. The pineal gland was large and œdematous.

The brain throughout was exceedingly soft. The crura, pons, cerebellum, and medulla partook in general of the character of the hemispheres.

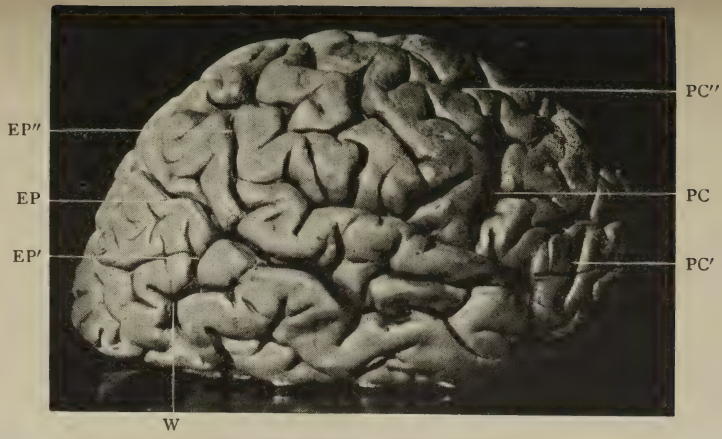
The brain—all fluid having been allowed to drain away—was weighed, the weight equalling fifty-seven and a half ounces. Its great size was very striking.

The most interesting feature, however, in connection with this examination was the study of the convolutions. Taking up, to begin with, the left hemisphere and studying its lateral surface, we notice at once an unusual degree of confluence between various fissures, and also the presence of a large number of abnormal fissures. For instance, the fissure of Rolando is superficially confluent with the Sylvian, being separated from the latter by the merest strip of tissue. The precentral fissure is freely confluent with the Sylvian. The interparietal is confluent with a small transverse fissure cutting deeply into the *pli de passage supérieure*



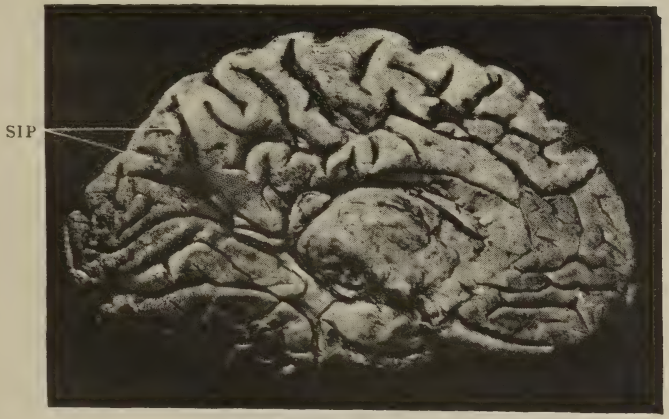
LEFT HEMISPHERE.—LATERAL SURFACE.

PC = precentral fissure. PC′ and PC″ = unusual precentral fissures. EP = external perpendicular fissure. EP′ = vegetative repetition of EP. W = Wernicke's fissure. W′ = vegetative repetition of W. EP and W, taken together, form an irregular arc. EP′ and W′ also suggest an incomplete second arc.



RIGHT HEMISPHERE.—LATERAL SURFACE.

EP = external perpendicular fissure. EP′ and EP″ = vegetative repetitions of EP. W = Wernicke's fissure. As in the left hemisphere, EP and W constitute an arc. PC = precentral fissure. PC′ and PC″ = unusual precentrals (vegetative repetitions). In advance of W is a short perpendicular fissure which suggests a second Wernicke.



LEFT HEMISPHERE.—MESIAL SURFACE.

SIP = superior internal *pli de passage*.

RIGHT HEMISPHERE.—MESIAL SURFACE.

SIP = superior internal *pli de passage*.

externe, and evidently a detached portion of the parieto-occipital fissure. This is an ape-like characteristic. Other evidences of confluence can be seen in the parallel fissure, which is confluent with a number of perpendicular fissures.

Some of the abnormal fissures of the lateral surface are of morphological significance; others must be regarded as purely pathological. Studied from before backward, they are as follows. First an abnormal perpendicular fissure close to the apex of the frontal lobe. It starts from the anterior portion of the third frontal convolution, which it incises; then passes in a more or less perpendicular direction upward, prevents the normal development of the second frontal fissure, cuts deeply through the second frontal convolution, and finally fuses with the first frontal fissure. Secondly, the fissure occupying the position of the normal precentral fissure presents a very unusual appearance. A fissure confluent with the Sylvian passes upward and joins as normally the second frontal fissure. At this point, however, it becomes more like a cleft than a fissure, and deeply incises the second frontal convolution, becoming all but confluent with the superior frontal fissure,—is in reality superficially continuous with it. Again, at the point of junction with the second frontal fissure, two abnormal fissures arise, one passing obliquely downward into the operculum, the other obliquely upward and backward into the posterior portion of the second frontal convolution. An irregularly stellate arrangement is thus produced.

As occasionally found in other brains, the superior frontal fissure is confluent with a perpendicular fissure, really a precentral fissure, just in front of the fissure of Rolando. It is large and deep. We thus have in this frontal lobe three well-marked perpendicular or precentral fissures. The significance of this fact will be presently discussed.

The parietal, temporal, and occipital lobes also present a number of remarkable fissures, all of them having a more or less perpendicular direction. For instance, directly opposite the parieto-occipital fissure is found an external perpendicular fissure, homologous doubtless with the corresponding fissure in the apes. It runs obliquely downward, and in the lower portion of its course it is confluent with the parallel. In advance of and pursuing a similar direction to this fissure, and separated from it by what is apparently the angular gyrus, is another perpendicular fissure. It separates the angular gyrus from the supra-marginal lobule, is shallow and blind at both ends, though at first sight it appears as though confluent with the Sylvian. It is doubtless a "vegetative repetition"* of the first-mentioned perpendicular fissure.

A deep and well-marked Wernicke's fissure is present. It pursues an almost perpendicular course downward, immediately beneath the first-mentioned external perpendicular fissure. Strange to say, in advance of it—parallel to it, though separated from it by a large block of tissue—is found another vertical fissure, corresponding doubtless to the above second-described external perpendicular fissure, and, like it, a "vegetative repetition." This fissure deeply bisects the temporal lobe, and is confluent with the parallel.

On the occipital lobe the interparietal terminates, as normally, in a transverse occipital fissure, and below this a parallel "vegetative repetition" (a second occipital fissure?) is found.

The mesial surface of this hemisphere, upon being examined, proves no less interesting. The calloso-marginal fissure is more complex than usual by a tendency to confluence with fissures pursuing transverse or perpendicular directions. The quadrate lobule is large, and contains an unusually deep, irregularly H-shaped fissure. The most remarkable feature of the mesial surface, however, is that the parieto-occipital fissure is bifurcated. This bifurcation is produced by the development of a highly aberrant convolution, the *pli de passage supérieure* INTERNE of Gratiolet. This remarkable convolution the writer had never seen developed to the surface in any human brain, with the single exception of that of an epileptic; in which, however, it was comparatively small. This internal superior *pli de passage* is normally developed in the anthropoid apes, notably the chimpanzee. In the present instance it has the shape of a large equilateral triangle, encroaching markedly upon the cuneus. The latter is relatively small. The calcarine is long and sinuous, and termi-

* See Proceedings of the Academy of Natural Sciences, Philadelphia, 1878. Communication by Dr. A. J. Parker.

nates without bifurcating on the apex of the occipital lobe. It is superficially confluent with the fissura hippocampi, as the gyrus fornicatus is at this point submerged. Beneath the calcarine is found a shallow "vegetative repetition." A deep collateral fissure is present.

The right hemisphere resembles in a general way the left. It differs, however, as follows. In the first place, the tendency to transverse fissuration, so well marked in the left hemisphere by the presence of three (precentral) perpendicular fissures, is much less pronounced on this side. A faint depression alone marks an analogy to the first precentral fissure of the other hemisphere; the second (the normal) precentral is not confluent with the Sylvian, and, though deep, is not by any means as complex as its fellow on the opposite brain; while a third precentral, though present, is much smaller than its opposite fellow.

The fissure of Rolando is superficially and irregularly confluent with the Sylvian. The fissure of Sylvius, though short, presents nothing worthy of note beyond a superficial confluence with the anterior portion of the interparietal. The latter, with the exception just mentioned, giving off a small retro-central branch, pursues an average course, winding around an unusually large *pli de passage supérieure externe*, and finally terminates in a small transverse occipital. The parallel fissure is remarkable for being confluent with no less than three external perpendicular fissures. The middle and principal one of these arises opposite the parieto-occipital fissure, and, passing downward and forward, becomes confluent, as just stated, with the parallel. The one anterior separates, as upon the opposite hemisphere, the angular and supramarginal convolutions. It is also deeper than its opposite fellow. It runs directly downward, and is confluent with both the interparietal and parallel fissures. The third and posterior runs downward and forward, approaching more nearly a horizontal direction. It is deep, but terminates superficially in a well-marked Wernicke's fissure. This last-mentioned fissure is remarkable for being *directly continuous* with the middle or principal external perpendicular fissure. By this means the occipital lobe is sharply demarcated from the parietal and temporal lobes, thus reproducing the condition found in the apes.

Upon the mesial surface the same tendency is observed, as in the opposite hemisphere, of confluence of the colosso-marginal fissure with transverse or perpendicular fissures, though it is here less marked. The quadrate lobule again is very large, and marked by unusually deep stellate fissures. As upon the opposite side, the parieto-occipital fissure is bifurcated. A superior internal *pli de passage* is present, though it is very much smaller than upon the opposite side. Strangely enough, the superior external *pli de passage* is relatively very large on this side, whilst upon the opposite hemisphere, in which the *internal* convolution is so large, the *external* convolution is relatively small. The cuneus is a trifle larger than upon the opposite side. The calcarine is smaller, and less sinuous, but terminates without bifurcating, as in the opposite brain. The calcarine, however, *passes directly into the fissura hippocampi*, the gyrus fornicatus being here entirely absent. This is another striking ape-like characteristic.

In taking a general glance at this remarkable brain, it is evident, as pointed out by the writer in a recent paper on "Epileptic Brains," that two powerful factors have combined to produce this distorted and aberrant organ. In the first place, there was in this brain a distinct morphological factor: that is, the line of development, instead of following the direction usual in the human brain, was deflected early in its course, so as to reproduce more or less perfectly structures and conditions found in the apes. The term "arrest of development" will hardly cover the production of ape-like structures such as instanced in the superior internal *pli de passage*. It seems, indeed, as though arrest of structure in one part necessitated the hyperdevelopment of some other part. Now, forcible arrest of growth readily presents itself as an interfering or deflecting cause. Let us reflect a little further, and the difficulties may solve themselves.

What is the meaning of this thin, large, and dilated skull? What is the meaning of this transverse fissuration of the brain? Evidently the two go hand in hand. Evidently this large, excessive brain-mass developed under pressure, and transverse clefts, most marked at the two poles of the brain, were the natural result. But is this all? Why does this transverse fissuration simulate so closely the fissuration found in

the apes? Evidently those areas of the cerebral cortex in man which most distinguish him from the ape are of *late*—of *recent*—development. They represent, therefore, areas in which the developmental force, or growth-force, is relatively weak. Given, then, an interfering or repressive cause, these areas are the first to yield to the stress of circumstances. They remain undeveloped. *Their very absence, however, necessitates the reproduction of other portions, portions long disused, and therefore rudimentary or absent in the normal state.* In this way the writer would explain the production of such a wonderful structure as that represented in the *pli de passage supérieure interne* of this brain.

If this view be correct, the pathological factor is, after all, dominant, and in the present instance the condition of the skull and the evidences of inflammatory changes in the membranes certainly help to bear it out, as does also the microscopic examination. Sections were prepared by Dr. Ida V. Reel. They were taken from the paracentral lobules of either hemisphere. They show, in certain portions of the white matter, decided increase of the neuroglia, dilatation of the periganglionic lymph-spaces, with consequent or concomitant shrinking of the cells, an increase in the number and tortuosity of the vessels, here and there a capillary with its walls infiltrated with nuclei, and sometimes a dilated perivascular space. In one and the same section, however, are found cells which present nothing abnormal whatever. Doubtless enough of such tissue was present to maintain cerebration.

The writer refrains from making comments on the mental condition of the possessor of such a brain. He does not, however, believe that any one with a full knowledge of the facts would predicate of such a brain a normal mind, and yet such an individual might be perfectly able to appreciate the consequences of crime, to differentiate between right and wrong, and to be, in the eyes of the law, a responsible individual. With this, however, the pathologist has nothing to do.

THE HOSPITAL OF THE JEFFERSON MEDICAL COLLEGE has just come into possession of a bequest of a hundred thousand dollars, through the hands of Professor William S. Forbes, who for several years had held the amount in trust from the estate of the late Mr. Louis Audenried, of Philadelphia.

THE DUTY OF THE STATE TO THE INSANE.

Read at a joint meeting of the Philadelphia Neurological and Medical Jurisprudence Societies, January 24, 1887,

BY EDWARD N. BRUSH, M.D.,

Senior Assistant Physician, Pennsylvania Hospital for the Insane, Male Department.

THE embarrassment of my situation this evening will, I hope, be appreciated, and the crudity of my remarks be excused, when I say that only five days ago was I made aware that a paper was expected from me.

The subject which I have chosen is one to which I have given some thought and investigation, but the time has been too brief to place my ideas in orderly relation to each other, or to gather the scattered host of authorities and references which I might otherwise marshal to my support.

What I have to present, therefore, is thrown out more with the hope of provoking discussion and interest in the subject than with the idea of enlightening any of the members of these two Societies, so many of whom have had larger experience and achieved riper judgment than I have.

There can be no question of the duty of the state to care for its wards in accordance with the best judgment of the time, and to keep pace with the progress which a better knowledge is making for their protection, relief, or, if possible, cure.

Following, as we so closely do in many other things, the English law and practice, it has come to be an accepted fact that those who, from birth or by reason of the accidents and ills of life, are *non compos mentis*, are peculiarly deserving of the watchful guardianship of the state. The earliest English laws had only to do with the estates of these unfortunates, which were the king's prerogative, and out of which their owners were, by legal provision, provided for in accordance with the customs of the time. It came to be observed in time that enactments which had regard only to the estates of the insane did not meet all the requirements of the case, and that the persons as well as the estates needed care and custody. Having in view always the "liberty of the subject," which could not be violated without due process of law and for good and sufficient reason, statutes were framed which permitted the restraint of the insane, confining the application at first to those only who were manifestly dangerous to themselves or to others. Gradually the ques-

tion of confinement for curative purposes came to be considered, and its necessity admitted, until at the present time all civilized countries recognize in some way the legality of commitments to asylums and hospitals of those of the insane who are not of necessity dangerous, but whose detention is justified by the exigencies of treatment.

It is the natural outgrowth of all theories of government which pretend to be paternal in form that the state should afford to its citizen protection, and particularly so "when he is without the use and enjoyment of his mental powers." The means to this end will always be a fair measure of the degree of advancement in civilization attained by the state.

In caring for her insane wards the state should seek those means which shall best accomplish—

1. The protection of the insane from themselves and from the cruelty and neglect of others.

2. The protection of its sane citizens from the violence of the insane.

3. The restoration of the insane to a condition of sanity.

I have placed these objects in the order in which they are usually enumerated, and in which the law usually regards them. In the order of their importance they should be reversed, for the restoration of the insane to a condition of sanity implies the accomplishment, in the course of its attempt, of all the others.

It is, I think, a fact which cannot be controverted that the insane are best cared for and their recovery most surely accomplished in organized hospitals devoted to their special treatment. This is certainly true of those of the indigent and pauper class, who cannot afford to make the arrangements which would otherwise be necessary, and I feel confident that the hospitals of the future will afford to all classes such accommodations that private care will be as unnecessary as it is often unwise.

To insure the proper treatment of its insane wards it becomes the duty of the state to make such provisions that all its insane can find ready and proper treatment in its hospitals.

In England and Wales the census of 1880 returns, on the 1st of January, 71,191 lunatics, idiots, and persons of unsound mind. Of these there were in county and borough asylums, hospitals, and district asylums, 44,035 paupers, 3513 private patients, and 655 criminals; in licensed houses, 1084 paupers, 3404 private patients, and 61 criminals; in workhouses (corresponding to our almshouses), 11,991 paupers; residing with relatives and others, 5980 paupers and 468 private patients.

It will be seen that of the 63,090 pauper insane, 45,219 (or nearly seventy-two per cent.) were in hospitals or licensed houses, and but 11,991 (or about seventeen per cent.) in the insane wards of workhouses, and these are, as required by the Commissions of Lunacy, only of the most quiet and harmless kind. Of the private insane, 7385 in all, all but 468 were in hospitals or licensed houses.

Let us compare this with the condition of the insane in the State of Pennsylvania, as shown by the United States census of the same year. Of the 8304 insane in this State, as enumerated in the census of 1880, but thirty-six per cent. were in organized hospitals, eighteen per cent. in almshouses, and forty-six per cent. at home. Massachusetts had sixty per cent. in hospitals, nine per cent. in almshouses, thirty-one per cent. at home; New York, fifty-seven per cent. in hospitals, eleven per cent. in almshouses, and thirty-two per cent. at home. Of all the large States, Pennsylvania had the smallest proportion of her insane in hospitals, and the largest in almshouses and at home.

Of all the insane in the United States in 1880, nine per cent. were resident in this State. Of all the insane in hospital but seven per cent. were in Pennsylvania, while sixteen per cent. of all those in almshouses were in Pennsylvania.

Here is a condition of affairs that may well attract attention. I am happy to say that since 1880 a larger number of insane have found accommodation in the hospitals and asylums of this State; but the number is still far below what it should be. According to the second annual report of the Committee on Lunacy of this State, its hospitals afforded accommodation for but 44.5 per cent. of the insane. As the hospital accommodations have not been increased, the percentage at this time is much smaller, owing to the natural increase and accumulation of chronic cases.

Having made suitable provision for the insane, the question of the legal admission and detention of this class is of next importance.

The majority of the enactments in force in the United States and, indeed, in England to-day appear to have been framed under a most remarkable suspicion that the citizens of the state were in constant danger of being spirited behind the bars of an asylum and forever disappearing from the view of mankind.

So strong appears to have been the conviction that medical men were ready to conspire to commit their fellow-citizens to asylums for the insane, and that the medical officers of asylums were waiting to aid and abet them, that the law of this State to-day directs that each examiner shall see and examine the patient separately, thus debarring each and the suspected lunatic from the benefits of conjoined examination and consultation.

Hear what an eminent English author, for many years Lord-Chancellor's Visitor in Lunacy, says upon this point, which also finds a lodgement in English lunacy law:

"It seems, if one thinks of it, a strange embodiment of jealousy and distrust; for in other instances where the opinions of two or more medical men are required, the opposite course is taken in order to secure the great advantage of combined observation. When in any other form of disease it is desired to confirm the opinion of one medical man by that of another, what would be thought of the wisdom of a proposal that each man should examine the patient separately? When medical men examine a patient together, they usefully check each other, and are of the greatest mutual assistance in observing correctly and estimating rightly the symptoms of disease, a consideration of the greatest importance in cases of mental disease, whereof the main symptoms are words spoken by the patient, which often convey a different meaning to the minds of different people. If the lunacy laws had not been imbued with distrust of the medical profession, they would never have contained an enactment abrogating all the advantages of medical consultation. Rather would they have enacted that the examination should be a joint one, the opinion concurrent, and the report thereof, or certificate, mutual."

In view of the assertion and implication that the insane are improperly committed, it may be of interest to examine the testimony of the late Lord Shaftesbury, for over forty years the head of the English Lunacy Commission,—a man who was eminently entitled to be called the friend of the insane, and whose whole life was spent in improving their condition.

In his testimony before the Parliamentary Committee of 1877 he says, of the one hundred and eighty-five thousand certificates of lunacy that had passed through the hands of the Committee from 1859 to 1877, that he is "quite certain"—I quote his own language—"that out of the one hundred and eighty-five thousand there was not one who was not shut up upon good, fair, *prima facie* evidence that he ought to be under care and treatment." Speaking further upon this subject of commitment, he said that, in his opinion, sufficient safeguards were thrown about the liberty of the subject.

If the insane are to be cared for with their recovery in view, every obstacle, as far as practicable, should be removed from their early commitment to asylums and hospitals. Experience has taught that recovery is to be expected only when the case is placed early under treatment.

Sir James Coxe, long the head of the Scotch Committee on Lunacy, a body which has done all in its power to encourage early treatment, testified that every impediment which is thrown in the way of early treatment acts most prejudicially upon the patient by tending to render permanent the aberration. Referring to the experience of the Scotch asylums, whose large percentage of recoveries is due to the fact that early commitment is encouraged and facilitated by the law, he says, citing the example of the Renfrewshire asylums, where the highest percentage of recoveries and the shortest duration of treatment has been attained, that in these particular cases this is brought about by the fact that the directors of the poor can put a patient in the asylum without any difficulty, and that discharge is equally easy.

Dr. Harrington Tuke, before the same Committee of 1877, testified that, in conjunction with the late Dr. Conolly, a man who certainly would not unadvisedly suggest asylum-restraint, he had examined the statistics of three asylums with which they had been connected, and found that seventy-seven per cent. of cases treated while the insanity was of less than three months' duration recovered. Those treated at later periods diminished in absolutely

geometrical ratio until, after twelve months' duration, it was something like twelve per cent. of recoveries.

These statistics bear out some calculations of my own, made at the State Lunatic Asylum at Utica five years ago, and published in the Asylum reports. Of the admissions to that institution for ten years, aggregating four thousand one hundred and twenty-nine insane persons, thirty-two and a half per cent. recovered. Of those insane a year and over, but twelve and one-third per cent. recovered; while of the entire number insane under twelve months, forty-four per cent. recovered.

At this point reference may be proper to the unfortunate result of agitation concerning lunacy matters and the suspicion cast upon asylums and their management by newspapers, legislative committees, etc.

In New York State, the year 1878 marks the commencement of a series of most malignant attacks upon the asylum-system of the State, resulting in no less than five legislative inquiries, which have, I am happy to say, resulted in a vindication of the asylum officials and the lunacy laws of the State from the charge of improper commitment to asylum or unjust confinement or treatment therein.

The results as concerns the unfortunate insane were not so happy. For seven years (1872 to 1878, both inclusive) the average percentage of cases admitted to the asylum at Utica who were insane a year or more on reception was thirty-three and one-third. In 1879 it rose to thirty-five and one-half, and in 1884 it reached fifty-one and six-tenths, the average for the second period of seven years (1879–1885) being forty-five per cent. of practically chronic cases.

The second, third, and fourth reports of the Committee of Lunacy of this State will show that from forty-two per cent., or a little over two-fifths of the admissions, for the past three years to all the organized hospitals and asylums of the State, seventy-three and two-thirds, or nearly three-fourths, of all the recoveries were drawn.

These reports will also show that fifty-eight per cent. of the cases admitted to the hospitals and asylums were chronic cases.

What is the remedy? Primarily, it seems to me, the creation of a public sentiment in favor of hospitals and asylums. The removal as far as possible of the feeling of distrust and suspicion which now surrounds the subject is necessary to induce the friends of the insane to take advantage of the facilities offered them for treatment.

It is of course implied that the State shall furnish sufficient accommodations for its insane before asking its citizens to take advantage of them.

One great obstacle which lies in the path of early asylum-treatment is the objection which physicians have against signing certificates of insanity.

The law places upon them the onus of saying not only that the person examined is insane, but that he is a proper case for confinement. They are not protected in any way against the annoyance of suit for damages brought by unrecovered lunatics before ignorant and prejudiced juries. Many physicians in general practice, moreover, feel themselves without sufficient training and experience in the diagnosis of insanity to be able or willing, in the very earliest stages of the disease, to take the responsibility of diagnosis and certification. To obviate this, all medical schools should make instruction upon insanity a by no means unimportant part of their medical course, and attendance necessary to graduation. I speak with all due respect for the knowledge and diagnostic acumen of my medical brethren in general practice when I say that of one single form of insanity, one that is singularly regular and characteristic in its manifestations, I have not known a single case out of over two hundred and fifty to be recognized before commitment. I refer to paresis. The mental disturbance was appreciated, as evinced by the certificate, but the peculiar form was wholly unrecognized.

The fault was not with the physicians. They had never had occasion or opportunity to receive instruction in these cases.

Another element which is active in preventing early asylum-treatment is the indisposition of poor-relief officers, overseers, and others to grant orders of admission until some overt act or threatened violence makes detention necessary, and too often in such cases even the wish to stand well with an unthinking constituency by a show of economy results in the incarceration of acute cases in almshouses. The law should make such action a misdemeanor.

In the State of New York, except in the

counties of Kings, New York, and Monroe, there is no place except a State asylum where a case of acute insanity requiring public relief can be legally detained.

As far as proper care is concerned, the pauper seems in the State of Pennsylvania to have the advantage. Persons who are able to pay the low rates of three and four dollars weekly are compelled to depend upon the charity of the incorporated hospital, as in their present crowded condition the State asylums cannot receive them.

The provision of the New York lunacy law in regard to the indigent insane not paupers might, it seems to me, be well imitated.

I am informed that the necessary exclusion of these cases has resulted, in part, in the at present low percentage of recoveries in the hospitals of this State.

It seems a crying wrong that a small taxpayer who has assisted for years in supporting the hospitals of the State must, when becoming insane, be refused the benefit of treatment because his place is occupied by a pauper, for whose recovery, in four cases out of five of those now under care, there is no expectation.

In the thirty-eighth annual report of the Commissioners in Lunacy for Scotland reference is made to exactly this condition of things, which was found to exist in one of the royal asylums (institutions corresponding somewhat with our State asylums). The Commissioners say of this asylum that at present the public are suffering by the presence in the asylum of pauper patients, who might, as they point out, be as well provided for elsewhere, being quiet chronic cases. As a consequence, twenty-seven private patients at low rates were refused. At the time of the visit (of the Commissioners) two letters applying for admission were seen, one of which from a mechanic points out that, so far as he can see, but two classes were provided for, the very rich and the very poor. The Commissioners very emphatically animadvert upon this condition of affairs.

The state owes a duty to all classes of her citizens to so provide that they may feel assured that in the event of becoming insane they shall be properly cared for.

Not by any means the least of the duties of the state is to provide, by Commissioners or otherwise, such a system of inspection and visitation of all places where the insane are confined that their friends shall be afforded a means of satisfying themselves of the proper conduct of such places.

Such a Commission is or should be an educator of the people,—a bulwark on the one hand against unjust charges concerning asylum and hospital management, and on the other against the improper care and custody of the insane.

Imbued with a right spirit, they are strong factors in the establishment and maintenance of a proper system of hospital care, as witness the course of the English and Scotch Commissioners, who have been a real help to asylum physicians instead of captious critics, and who have by their course aided very materially in promoting the prompt and proper care of the insane. So strong has become the opinion of the English Commissioners in favor of early treatment that when it was recently proposed to throw, by an amendment of the law, increased difficulties in the way of early commitments, the chairman of the Commission resigned rather than by retaining office seem to sanction such a change.

The Lunacy Committee of this State is, I believe, endeavoring to emulate the example of its English prototype. Under our more recent laws, which in some respects are not harmonious in all their relations, and with few American precedents to guide it, and an incomplete asylum system to work with, the Committee may not in all things accomplish at once what might be desired. Its hands should be sustained, however, and time and wider experience may be trusted to work much good.

REPORT ON RECENT PROGRESS IN OBSTETRICS AND GYNÆCOLOGY.

BY W. H. H. GITHENS, M.D.

PILOCARPINE IN PUERPERAL CONVULSIONS.

IN the July number (American reprint) of the *London Lancet*, Dr. James Murphy reports six cases of the successful use of pilocarpine in puerperal convulsions. He injects one-third of a grain hypodermically. His results were prompt and satisfactory; all his cases recovered. He has found it necessary in some cases to repeat the dose in six hours. In a previous number of the *Lancet*, Dr. Harrocks had reported the successful use of this remedy; and in the *American Journal of Obstetrics* for December, 1883, two cases are care-

fully reported by Dr. Murphy. This treatment is by no means new, having been tried by Bidder as far back as 1872.

TECHNIQUE OF THE SANGER OPERATION.

In the *Centralbl. f. Gynäcologie*, No. 32, 1886, Leopold formulates the following rules as the result of his experience with the Sänger operation:

1. The patient should be examined and disturbed as little as possible before the operation. The internal and external genitals should be washed with sublimate solution (one to two thousand), or a three-per-cent. carbolic-acid solution.

2. The operation should be performed as early as possible, at the farthest by the end of the first stage of parturition.

3. The operator must be assured of efficient assistants, who have been previously instructed in all the details of the operation.

4. The uterine section should reach only to the movable peritoneum, and ultimately be prolonged to the fundus.

5. After the removal of the child and before the separation of the placenta, the uterus is removed from the abdominal cavity, and

6. Hemorrhage is checked by compression with an elastic ligature and finally by manual compression.

7. The uterine wound is sutured with silver wire, the decidua being avoided. Coaptation of the muscular surfaces is best effected when, before the sutures are drawn up, the uterus is compressed laterally. The superficial sutures are best made with thin silk.

8. The elastic ligature is now removed, and the further procedures follow the rules of a laparotomy.—*Medical News.*

PROLONGED DILATATION OF THE UTERUS.

Vulliet (*Arch. de Tocologie*, October 30, 1886) has submitted to the Paris Académie de Médecine a paper on a new method of dilating the uterine canal for diagnostic and therapeutic purposes, which gives an opportunity to inspect the diseased endometrium and to apply medicaments directly to it. The dilatation may be kept up indefinitely without injury to the patient.

Modus Operandi.—The patient is placed in the knee-chest position, the os exposed by the aid of a Sims speculum, and bits of cotton saturated in an ethereal solution of iodoform (one to ten) are passed into the uterine cavity. These tampons vary in size from that of a pea to that of an almond, and have each a piece of thread attached; they are introduced by means of a sound until the cavity and canal are filled up to the os externum. After forty-eight hours they are withdrawn and a fresh lot introduced, and this operation is repeated eight or ten times until the cavity is so dilated that it is visible throughout.—*New York Medical Journal*, December 25, 1886.

OVARIAN ABSCESS AND PYOSALPINX.

Dr. Imlach: *Liverpool Medico-Chirurgical Journal*, 1886. The author considers that it is a mistake to call the ovaries and tubes *uterine appendages*. It would harmonize better with modern physiology and pathology to call the uterus an ovarian appendage. The tubes may become infected from the ovary or from the uterus. Menstrual discharge is not found in healthy tubes, ovarian hemorrhage being always pathological and leading probably to tubal disease. In *hæmatosalpinx* there is always distention; the coats of the tube may be thin and transparent, or the muscular coat may become greatly hypertrophied. The distention results from matting together of the fimbriæ and closure of the uterine opening of the tube. The large proportion of tubes distended by blood results in pelvic hæmatocele. If the ostium uterinum be open, cure may be effected without operation.

Hydrosalpinx.—The tubes are closed at both ends, and contain from one to five ounces of thin sero-albuminous fluid which rarely coagulates on standing. The mucous and muscular coats of the tube become nearly obliterated. The pain from serous distention is great, and Imlach has operated for this condition twelve times without a death.

Pyosalpinx.—The *acute* form Imlach has never met with at operation, although he has seen it post mortem. The *chronic* form has many varieties. If the tubes are not occluded they feel like thick cords, and contain a few drops of pus or muco-pus. Sometimes the tubes feel as if two or three beans were contained within them; these are thickened and dilated chambers containing thick pus or dark-brown blood. The infundibulum may be distended with pus, the uterine half being simply somewhat thickened, or the entire tube may be filled with putrid pus.

Ovaries.—Both tubes may be distended with pus or other fluid, and yet the ovaries show little or no sign of disease. Inflammation of the ovary consists in the pathology of its cysts. Oöphoritis may exist without disease of the tubes. Both hypertrophy and atrophy of the ovaries are found. When the physiological cysts of the ovary contain a drachm or more of dark fluid blood, or a more or less disintegrated corpus luteum floating in blood, the ovary may be termed *hæmatocystic.* This condition is found in hæmatocele and with pyosalpinx. In a *hydrocystic* ovary the Graafian follicles have become large watery cysts. This condition results from prolonged lactation and poor food, and may be cured by rest and good feeding. *Pyocystic* ovaries contain from a few drops to an ounce or so of pus or a mixture of blood and pus. The tubes may be simply congested, but usually they are thickened and purulent.

Sooner or later, general or local peritonitis is set up by overflow of the tubal contents into the peritoneal cavity.

THE ETIOLOGY OF SALPINGITIS.

Martin (*Centralbl. für Gynäkologie*, No. 45, 1886) reports the results of his observations in two hundred and eighty-seven cases of diseased Fallopian tubes. In over one-half of the number the inflammation began in and extended directly from the uterus; twenty-five per cent. were of puerperal origin; five-sixths were due to gonorrhœal infection, and one-sixth to tuberculosis. The left tube alone was affected in one hundred and thirty-eight cases, the right alone in fifty-eight, and both in ninety-one. The entrance of micro-organisms of puerperal sepsis, gonorrhœa, tuberculosis, or actinomycosis is followed by suppuration. The prognosis is not so gloomy as it has been represented: the inflammation may subside and a perfect cure follow, so that the patient subsequently becomes pregnant. If palliative treatment fails and the symptoms are very severe, an operation is justifiable.—*New York Medical Journal.*

FŒTAL INDICATIONS FOR THE USE OF THE FORCEPS.

S. Marx, in the *American Journal of Obstetrics* (November, 1886), details two cases of rupture of the uterus in the puerperal state. In the course of the paper he remarks,—

"If the forceps were more applied for the child's safety, a good deed would be done. The three symptoms which indicate danger to the fœtus are:

"I. Slowing of the heart's action between and during the pains, say a fœtal heart of eighty, or a gradual sinking of the tones during each pain, or especially where the heart-tones have been good and gradually cease. If the sounds sink to eighty or seventy in a pain, but rise to one hundred and twenty or one hundred and forty in the intervals, there is no danger to be apprehended. But if the heart-tones should even be one hundred for a considerable time, the case demands the entire attention of the physician, and under these conditions, especially if the woman has previously borne dead children, it would be well to terminate the labor, providing the condition of the parts allowed it.

"II. Escape of meconium is a symptom of great importance. It shows that there is a paralysis of the voluntary muscles, and especially the sphincter ani, from some cause, and most frequently this is carbonic-acid gas poisoning. Should this symptom be present with a fœtal heart of eighty, the most urgent symptoms are presented to the accoucheur for a speedy delivery. I have yet to see the case in which the child was not to some extent asphyxiated where these two symptoms were present.

"III. The umbilical souffle is a symptom, when present, not to be forgotten. It reminds one of a soft, blowing murmur synchronous with the fœtal heart. It is caused by the cord being subjected to pressure, either from being around the child's neck or around its body or pressed against the uterine walls: therefore it should be found in every case where it is suspected that the cord is being pressed upon."

PROPOSED MODIFICATION OF PORRO'S OPERATION.

Before the Gynæcological Society of Chicago, August 20, 1886, Dr. John Bartlett read a paper proposing an important modification of the Cæsarean section: "The operation proceeds as in Cæsarean section till the child is removed, the actual cautery being used in opening into the womb. Then, instead of dragging the womb out of the abdomen through the abdominal incision, it is dragged out of that cavity through the vagina. The operator passes a Wells's clamp, somewhat

modified in its prehensile surfaces and properly curved in coincidence with the parturient canal, to the fundus of the uterus, and there secures a firm grasp into the uterine tissues. By traction upon these forceps, and pressure and suitable manipulation from above, the fundus of the uterus is depressed into the body of the organ, and dragged through the cervix into the vagina to produce complete inversion. The clamping-wire is immediately adjusted, and excision of the uterus and appendages effected at a suitable distance from the vaginal juncture. . . . The advantages are:

"1. That the abdominal cavity is thoroughly closed, the abdominal incision not being embarrassed by the presence of the large pedicle. By the process of inversion the pedicle is placed outside of the abdominal cavity, while what may be termed the uterine inlet made into the peritoneal sac is closed by the clamping-wire opposing serous surface to serous surface.

"2. The relation of the parts is more natural and less strained than in the status in which Porro's method leaves them.

"3. In the event of drainage becoming necessary, the effecting of an opening for a tube can be accomplished more easily and safely than in Porro's plan."—*American Journal of Obstetrics.*

ADMINISTRATION OF DRUGS DURING LACTATION.

H. Fehling: *Archiv f. Gyn.*, xxvii., iii. A series of interesting experiments with various drugs administered during lactation are herein described, and the effect on the infant noted. The results obtained were as follows:

Salicylate of Soda.—From one to three grammes of this drug were given to the mother, and the infant put to the breast in from one to three hours afterwards. The urine of the mother and that of the child were then examined in a series of seven cases, with the result that the drug appeared in the urine of the child if nursed one hour after the administration of the drug, and continued present up to twenty-three hours.

Potassium Iodide.—One to two grammes administered to the mother: iodine uniformly detected in the urine and milk; it appeared in the milk at the end of twenty-four hours, but did not appear in the urine of the infant until seventy-two hours had passed.

Potassium ferrocyanide did not appear in the urine of the child, but did in that of the mother.

Iodoform was used over the perineum and vagina post partum: the characteristic reaction could be detected in the milk and urine of the mother, but did not affect the health of the child.

Mercurials.—Experiments on animals gave varying and uncertain results. The long-continued administration of mercurials to the mother may affect the infant.

Hydrochloric, acetic, and *citric acid* had no effect on the milk or the child.

Morphine given hypodermically had no determined effect on the child; the same may be said respecting chloral.

Atropine.—From 0.001 to 0.005 gramme given hypodermically to the mother caused in the majority of the cases wide dilatation of the infant's pupils, but this was the only effect. It is safe to give belladonna in the usual doses to the nursing mother.—*American Journal of Obstetrics.*

A CASE OF COMMINUTED AND DEPRESSED FRACTURE OF THE FRONTAL BONE, WITH RECOVERY AFTER TREPHINING.

BY T. H. ANDREWS, M.D.

GEORGE S., æt. 24, was kicked in the centre of his forehead by a mule, while working on a farm, on the 3d of December, 1886, producing a compound comminuted fracture of the frontal bone. The line of transverse laceration made by the animal's iron shoe was about two inches long, midway between the line of the eyebrows and the border of the scalp.

The attending physician, Dr. J. A. Crewitt, of Newtown, Bucks County, on his arrival found the patient in a semi-unconscious state, though for the first thirty minutes following the accident the man was said to have been profoundly unconscious. The doctor made several unsuccessful attempts to elevate the depressed fragments of bone, but, not being fully prepared for the operation, and desiring assistance, he telegraphed to me and requested me to come at once. Sedatives and cold dressings were employed during the enforced interval while awaiting surgical treatment. Owing to the telegram not being promptly delivered, I was unable to reach the patient before eight o'clock A.M., De-

cember 4. I found the patient perfectly conscious: his pulse and temperature were normal. Upon examination I found the

wound as described above, the frontal bone being greatly comminuted. The largest fragment (the inferior portion), was overridden by the superior upper fragments, and was found to be firmly pressed upon the dura mater. All attempts at elevation of this fragment proving simply futile, the trephine was at once applied to the sound bone above the fractured surfaces, and a disk of about five-eighths of an inch was removed. This enabled us to introduce the elevator and raise the larger depressed fragment, thus permitting the other smaller portions to be successively removed. (The above illustration represents the actual size of the fragments removed, including the disk taken out by the trephine.) Great care was taken to leave untouched and as nearly perfect as possible the overlying periosteum. Numerous small clots were found in the wound and extracted. After surgical cleanliness had been made perfect, the wound was drawn together and sutured. Cold-water dressings were made, and the progress towards health was rapid and unvarying, with negative symptoms altogether, temperature and pulse being unaffected. The wound healed in five weeks.

To-day, eight weeks after the operation, the patient reported having been at his usual work, farming, for the last three weeks, and is in perfect ruddy robust health, as before the operation. He is not conscious of having had subjective symptoms in any form.

TRANSLATIONS.

Nocard and Roux on the Cultivation of Tubercle-Microbes.—At a recent meeting of the Paris Biological Society, MM. Nocard and Roux made the following communication concerning the cultivation of the microbe of tuberculosis. Since Koch's great discovery of the tubercle-microbe, all observers have been able to find its bacillus in tuberculous products. Thanks to Ehrlich's practical process, it may be said that no medical discovery has ever been so rapidly and so universally accepted. But, although it be easy to find the tubercle-bacillus, its cultivation offers some difficulty. The method of cultivation on gelatinized serum recommended by Koch is still generally used, and all those who have tried this method know how difficult it is to start the cultivation of the tubercle-microbe, and how long it requires to obtain a series of successive cultivations. Last year an effort was made to improve Koch's medium by adding peptone, sugar, and salt to the serum. Since then other researches have had better results, and it has been found that glycerin singularly favors the development of tubercle-bacilli, the serum being no longer necessary. Mediums that were looked upon by Koch as unfavorable to the culture of these bacilli, such as ordinary broth or broth solidified with gelatin, give an abundant vegetation when glycerin is added. The possibility of cultivation on gelatin to which a small quantity of glycerin, six to ten per cent., is added, constitutes an improvement on account of the transparency of the medium and the facility of its preparation. But this medium has other advantages: it enables the cultivation to be made in layers as easily as that of other microbes. Those submitted to the inspection of the Biological Society were cultivated in this way, and consisted of a considerable number of colonies, disposed in circular patches with well-defined contours. The most recent were transparent, the others becoming slightly yellow, and then brown, according to age, and having peculiarities permitting them to be distinguished in the midst of colonies of other microbes. There is reason to hope, says the author, that a similar result may be obtained by spreading tuberculous pus or sputum on the medium. When the microbe

is sown by pricking the gelatin thus prepared, the cultivation, which is scarcely appreciable along the course of the needle, becomes vigorous in contact with the air, under the form of a yellowish-white patch, somewhat salient, dry, with slightly-dentated contours. The cultivations obtained in the above manner were controlled by inoculation, and the animals became tuberculous quite as easily and as rapidly as by the cultivations obtained on pure serum, or on serum with peptone. On terminating, the author laid before the assembly a series of cultivations, all started on the same day and with the same seed. The cultivation obtained on pure serum was lean, dry, and scaly in those parts where the layer of serum was the thinnest. Serum with glycerin gave incomparably better results, and this was the case with gelatin to which glycerin had been added. An equally satisfactory result was obtained through the medium of ordinary broth with a little glycerin. It is not to be contested, said the author, that the cultivation in a liquid medium offers much greater facility for observing the conditions of the development of micro-organisms, and especially those which influence sporulation.

The Chemical Application of the Galvano-Puncture in Gynæcology.—Dr. Apostoli concluded a paper before the Société de Médecine de Paris (October 9) as follows:

The diseases of the uterus and its adnexa which are amenable to treatment by galvano-puncture are certain uterine fibromas, certain forms of chronic metritis, certain intra-uterine polypi, unilocular cysts of the ovary at their beginning, chronic abscess of the broad ligament, posterior perimetritis (subacute and chronic), peri-uterine blood cysts (hæmatocele), and extra-uterine pregnancy.

The general precautions to be used in the practice of vaginal galvano-puncture are the following:

1. As much as possible to avoid penetration of the peritoneum.

2. The possibility of an eventual foyer of suppuration is to be borne in mind, and precautions taken to secure elimination and resort to topical antiseptic treatment.

3. Short punctures (of one to two centimetres) are always preferable to deeper ones.

4. We should always, as a preliminary measure, sound and explore the bladder in every direction, in order to avoid wounding it or involving it in a deep eschar.

5. In all cases of lateral or posterior puncture we should explore by digital examination, in order to detect arterial pulsation and avoid perforation of the great vessels.

6. Rest in bed, from one to several days, should be required in all patients who have been subjected to galvano-puncture.

7. Before and after each puncture an antiseptic vaginal injection should be used, and a tampon of iodoform gauze placed in contact with the punctures, and allowed to remain until cicatrization is complete.

8. Sexual relations are to be prohibited during the treatment.

Virulence of Tuberculosis and Scrofula.—At a recent meeting of the Académie des Sciences, M. Arloing presented some remarks on the virulence of tuberculosis and of scrofula. M. Arloing had already demonstrated that pulmonary tuberculosis affects guinea-pigs and rabbits, while true glandular scrofula produces no lesions whatever on the latter animals. He now asks, Might not the virulence of scrofula be augmented to such a degree as to permit the infection of both these animals?

Experiments show that the passage of scrofula through two generations of guinea-pigs does not increase its virulence in respect to rabbits, and is not perceptibly modified in its action upon the former animals. The result is different with real tuberculosis in its attenuated forms, such as is met with in local tuberculosis: the organism of guinea-pigs augments the virulence of the enfeebled tuberculosis virus, while it seems to have no influence whatever on the virus of glandular scrofula. This fact justifies the difference experimentally established between the two morbid states. If it has not yet been proved that they are caused by two distinct kinds of virus, and if it must be admitted that they are derived from one sole agent, then the bacilli tuberculosis have different degrees of activity; at least it must be acknowledged that in true glandular scrofula they are farther from their primitive virulence than in local tuberculosis.

EDITORIAL.

RIGHT-HANDEDNESS AND AMBIDEXTERITY.

A VERY interesting communication read last November before the College of Physicians of Philadelphia seems to have reopened the question in medical journalism of the cause of right-handedness among the civilized races of man, which is as old as Aristotle. The paper referred to was read by Dr. Oscar H. Allis, and was entitled "Man's Aptitude for Labor in the Erect Position: with an Inquiry into the Agencies that Predispose to a very Universal Preference for the Right Leg and Arm." In his review of the mechanical points involved, and of the anatomical peculiarities of man which enable him to labor in the erect position, some important statements are made. The question of equilibrium is first considered. It is claimed that the tilting downward of the pelvis and the lumbar spinal curve are due to the position of the points of femoral support, and appear as soon as the child sustains the weight of the body in the erect posture upon its two limbs. Man is the only animal having two limbs exclusively for prehensile acts and two for support. The anatomical conditions are favorable to certain rotatory movements of the body above the hips; and, owing to the double curve of the spinal column and the peculiar articular relations of the vertebræ, it is seen that such rotation is not only possible but absolutely necessary for the movements of the body during manual labor. This twist, which is the chief motion of the dorsal region, gradually diminishes, until it is lost in the sacrum, or, if excessive, extends to the lower extremities, which are specially fitted to meet it. In this connection the suggestion is made that man, although he has only two legs, is in reality four-footed, since the ball and heel act alternately in progression and can accommodate themselves to different levels. A glance at the soles of the human feet shows how peculiarly they are adapted, when taken together, to grasping the earth and resisting any rotatory strain that may come from above. The architecture of the shoulder-joint also shows a marked adaptation in man to rotatory motion, as around a central axis.

In making inquiry into the agencies that predispose to a very universal preference for the use of the right leg and arm, Dr. Allis justly observes that man is the only animal that can possibly attain to *dexterity*, "because he is the only animal that has two hands exclusively for skilled work,—and skilled work demands *two* hands: one hand is not enough. One hand must hold the apple while the other pares it; one hand holds the chisel while the other uses the mallet. Each to its part, but both together for a definite purpose. The skill of the left, as assistant, is equal in every degree to the *dexterity* of the right." For this reason he feels that those are in error who believe in the desirability or possibility of ambidexterity. Since it is very early in life that the preference is shown for the right side, the efficient cause must be sought for in the infant. The explanation Dr. Allis finds in the position and disproportionate weight of the liver early in life, which lies mainly over the right leg, thus making it firm and stable, "and the use of the right arm, situated directly over the right leg, will tend less to the disturbance of the centre of gravity than would the use of the left arm."

We have dwelt upon Dr. Allis's views on account of the intrinsic importance of his contribution, and because he has not sufficiently insisted upon his strongest argument for the general preference for

the right hand. All left-handed people do not have transposition of the abdominal viscera, nor has it been demonstrated that such transposition is always accompanied by left-handedness. The mechanical explanation is therefore insufficient, though suggestive, and it should have due weight. On the other hand, the rotatory movements of the body during the performance of some kinds of manual labor, as in swinging the scythe or pushing the plane, are probably characteristic of the species, just as the stems of climbing plants tend to twist or revolve in a certain direction (and among which occasional exceptions are also found). Many movements, however, do not involve rotation of the trunk, and in these we believe it to be the fact that man is really ambidextrous; if the right hand be commonly employed, it is from choice, education, or fashion. It is true that in writing we usually hold the pen in the right hand, as we were taught at school, but when this member becomes disabled by accident or disease—writer's cramp, for instance — men frequently learn to write with the left hand. In playing musical instruments—the violin, flute, drum, or piano—ambidexterity is required, and may be attained by practice. We know of two instances in each of which the individuals can write equally well with both hands; and some ladies in sewing can use the needle indifferently in the right or the left hand. In the use of the type-writer by an expert there is no difference in dexterity observed between the two hands.

In considering the question of right-handedness, it is evident that a distinction might be made between movements which require rotation of the trunk and those that are confined to the arm and forearm: in the former the greater stability of the right side, buttressed by the liver, leads to the employment of the right arm for feats of strength or manual effort. On the contrary, when no support is needed, dexterity depends upon muscular agility and skill, and belongs to neither side exclusively. It is noteworthy that it is to actions of this kind that attention is usually directed in studying the phenomena of right-handedness, although, as we have shown, they may be performed equally well by the left hand by training and practice.

A PROSPECTIVE MONUMENT TO DR. BENJAMIN RUSH.

THE American Medical Association has appointed a committee, with resident members in most of the States and Territories of the Union, which is now actively engaged in collecting funds for the purpose of erecting at Washington a statue of Dr. Benjamin Rush, of Pennsylvania, the philosopher, physician, and patriot. Among the many artistic adornments of the national capital, where are found statues of Presidents, law-makers, generals and admirals, painters and sculptors, a monument to the American Sydenham would find appropriate place as the most distinguished representative of the medical profession which this country has yet produced.

The recent tributes of Benjamin Ward Richardson to Rush as philanthropist, orator, teacher, and man of letters, and of Tuke, who especially dwells upon his services to psychiatry, the address of Dr. Charles K. Mills before the Medico-Legal Society of New York on "Benjamin Rush and Psychiatry," and the eulogistic biographical sketch contained in the address of Dr. Weir Mitchell at the recent celebration of the centennial anniversary of the College of Physicians of Philadelphia, certainly indicate that the profession is at length beginning to take more interest in the career of this truly great American physician. In the words of Dr. Mills, "a Rush renaissance seems imminent."

What more fitting method could be devised of expressing this renewal of interest than by carrying out the purpose for which the committee was appointed? It

is proposed to raise the amount needed by dollar-subscriptions from the physicians and students of medicine in the United States. Contributions may be sent to Dr. John H. Musser, 3705 Powelton Avenue, Philadelphia, the resident member of the committee for this State. The reasons are obvious why the physicians of Pennsylvania should contribute handsomely to this fund.

INSANE AND CRIMINAL BRAINS.

ON another page we place before our readers the carefully-prepared report of the examination of a confessed murderer's brain, with photographic illustrations showing anatomical aberrations and defects of development which distinctly stamp the brain as inferior to the average type, and possibly place it among those which, as Benedikt has shown, are common among criminals. It would be evidently unfair to contrast the brains of professional criminals and outlaws belonging to the lowest social ranks with those of the highest type of civilization, and especially to assume that the latter is the standard to which others must conform. But, even when compared with the usual appearances of non-criminal brains taken from the same classes of society, it has been, if not fully demonstrated, at least rendered probable that certain classical changes of structure are commonly accompanied either by recognized insanity or by absence of the moral restraint upon conduct which the community requires of its members. Degradation of brain-structure is apt to be accompanied by degradation of life.

To the optimist, should this teaching find sufficient support, it will afford much encouragement: it leads him to hope that as man improves physically he will continue to improve morally, since much of the wickedness and crime recorded in the current history of the day may thus be explained by the accidental persistence of lower types of human organization, which are doomed to extinction. We are, nevertheless, far from subscribing to the opinion expressed during the discussion of the Guiteau trial, that "some insane people should be hung." On the contrary, we believe firmly that the logical and practical results of the study of this question must lead to the final abolition of the death-penalty in every civilized Christian community.

A NEW JOURNAL.

THE tendency to specialism in scientific work in Germany, and especially in those departments of such work which relate to medicine, is illustrated by the *Centralblatt für Bacteriologie und Parasitenkunde*, the advent of which we recently announced in these columns. Edited by Uhlworm, of Cassel, with the assistance of Leuckart, of Leipsic, and Loeffler, of Berlin, it is sure to represent in the fullest and fairest way the progress of knowledge in the field to which it is devoted. The initial number contains an original article, by Professor Leuckart, upon the Bothriocephalus, which is to be completed in the next issue, and a series of admirable, signed reviews of recent work in bacteriology. A department is devoted to new methods of investigation, new instruments, etc. Finally, a classified index to the recent literature of parasites and bacteriology concludes the number.

The editors are to be congratulated upon their success in the selection of their collaborateurs and the excellence of this number. It will be necessary not only to the special workers in this branch of biological research, but also to alert workers in every field of medicine who can read the German tongue. This pioneer comes from the other side of the Atlantic just at the time when the most widely circulated medical journal of this country has published a voluminous article "Against the Germ-Theory of Disease"! In the words of Hamlet,—

"Look here, upon this picture, and on this!"

NOTES FROM SPECIAL CORRESPONDENTS.

PARIS.

HYDROPHOBIA.—The discussion at the Académie de Médecine on hydrophobia was closed by Professor Peter, who gave further details of cases to prove his conviction that the Pasteur plan of medication, if such it can be called, is dangerous. In our last letter we spoke of the matter, and now, after hearing Dr. Peter's remarks and Professor Vulpian's eloquent reply to them, we must admit that it is still an open question. M. Peter clearly does not prove his case,—that is to say, that the deaths which occurred were due to the antihydrophobic inoculations; it is only proved that the individuals died of hydrophobia, and that the inoculations did not save them. Could he have shown conclusively that the dog or dogs in question which bit the patients were not mad, but were still alive and in good health, then it would have been certain that the patients died of a laboratory hydrophobia. The other side, headed by Professors Vulpian, Brouardel, Grancher, and others (in the absence of M. Pasteur, who is at Bordighera, in the South, for his health), have supported the great chemist to the best of their ability; but there is a growing feeling of distrust in regard to the method which only time and ample experience can allay. In the mean time the *Journal Officiel* publishes the eightieth list of subscriptions for the foundation of the "Pasteur Institute," and the total sum raised is now much over three hundred thousand dollars. They have also been given a part of the ground and old buildings hitherto used by the Faculty of Medicine for laboratories, but which are now being vacated by the Faculty, who are taking possession of the new buildings on the Boulevard St.-Germain. So the sinews of war and large laboratory-space will not be wanting to give M. Pasteur's system a fair trial. The result time only can tell.

Alimentary Régime.—This important study is the object of a new book by Professor Germain Sée, in which he details his ideas of the hygienic treatment of disease. Passing in review the usual forms of artificial alimentation, M. Sée condemns rectal alimentation, and, in fact, foods prepared with beef-teas and peptones and injected into the rectum have been found to be very little absorbed, so that this form of alimentation is certainly not only illusive, but, as rectal irritation follows so quickly upon it, it is almost useless. In regard to the buttermilk- and whey-cures so much used in Switzerland and other places, Sée, in speaking of their use in obesity, says that this cure is only a form of disguised inanition. Dyspepsia he considers is simply a defective chemical operation, and the serious study of this malady must be based on the examination of the chemical products of digestion: so this leads to the necessity for the evacuation of the stomach with sounds and the careful examination of the gastric juices. Of course this throws out, as not true dyspepsia, all the atonic or spasmodic disorders. For the true or chemical dyspepsia M. Sée recommends Vichy water, and then advises the use of tea as a drink in place of wine. In fact, all through this work Dr. Sée strongly recommends the use of tea as a drink. We fancy that he recommends it because he has seen much good come from substituting tea for wine by his patients; but it must be remembered that most French people never touch tea at all, and this may be one reason why so much benefit has been derived from its use. In any case, Professor Sée is a most enthusiastic advocate of its use; but we hope that this will not induce American or English physicians to order it to some of their dyspeptic patients who already drink more tea than is good for them. *Autre pays autres mœurs.* In phthisis, he says, "Tuberculosis commences often, and finishes almost always, by gastro-dyspepsia;" and he advises the following régime:

1st. Vichy water a half-hour before meals, to encourage the secretion of gastric juice.

2d. Also, before eating, a powder to absorb the gases created. (This powder consists of chalk and calcined magnesia.)

3d. The diet need not be uniform or systematic at all, and cold meats, fish, hot spiced dishes, and salt meat, even sausage, etc., can replace raw meat with advantage.

4th. Warm drinks, and, best of all, abundant stimulating infusions of tea.

5th. Finally, stomach-washing, if needed.

In gout, the alimentary régime is well known and has been well studied. Here again tea is recommended in abundance, because, says M. Sée, "theine is favorable to the organic changes, and warm aromatic liquids produce a sort of washing out of the urinary tubules which are the receptacle of the uric-acid deposits."

In diabetes he advises meats of all kinds, fats of varied sorts, and one hundred and fifty grammes daily of bread or potatoes, and the roots of green vegetables; and, as drinks, tea again, or coffee, without sugar, and Vichy water after meals.

As to obesity, the régime here should be restricted to what is the strict physiological necessity; and, as many would like to know just how much is the lowest, or rather the normal, amount of food one should take, we give Dr. Sée's figures: one hundred and twenty to one hundred and thirty grammes of nitrogenized principles, which may come from two hundred and fifty to three hundred grammes of lean meat (*i.e.*, about a half-pound of meat). Then eighty to one hundred and twenty grammes of neutral fats and two hundred and fifty of carbohydrates, which

can be furnished by four hundred to five hundred grammes of starchy food or of sugar; more than these quantities will increase obesity, which also is to be decreased by exercise. Drinks must not be suppressed, as some authors demand. On the contrary, in all cases they have to be increased in order to increase stomach-digestion and general nutrition. Here once more hot infusions of tea are recommended by our author, but alcoholic liquids and mineral waters are forbidden.

Heart-Diseases.—Whenever a cardiac patient presents the physical signs resulting from an insufficiency of the heart-valves, he should forthwith be put under certain hygienic rules. One of the most important of these is rest, or a "minimum of musculation," and in consequence of this an alimentary régime corresponding to the smaller quantity of heat lost and the slighter need of combustion. The food taken should not furnish more than the number of calories needed. In short, the heart's work should be limited to the smallest quantity possible. The moment there is œdema the milk-treatment is indispensable, as milk is the most powerful of all the diuretics.

Albuminuria.—The important point here is to watch the state of the skin and keep the pores open, by which means uræmic attacks may be warded off. Milk-diet, of course, is used, and he advises nourishment in small quantities at a time and often. Both the grape-cure and whey-cure are declared to be useless, or at least condemned on account of yielding very uncertain results. Clinical observation has recognized the good influence of oxygen-inhalations in albuminuria; the nutritive functions are increased, appetite is excited, the blood becomes richer in hæmoglobin, and the whole system is benefited. The induction is that these patients should seek for a mild climate with pure dry air, that is but little liable to variation of temperature; and the Mediterranean coast is especially recommended for this, as the Atlantic Ocean air is too stimulating, and mountain-climates have much too sudden variations.

Kéfir.—Professor Lépine, of the Faculty of Lyons, speaks of the therapeutic value of this substance in different affections of the stomach, for which he had lately given it to quite a number of patients. He makes no pretensions of its being a medicament, but calls it an aliment, for, like the koumyss, it is only fermented milk. Kéfir has the advantage of being more agreeable in its taste than koumyss. For hundreds of years, the Tartars who live in the Northern Caucasian mountains have prepared a drink, which they call kéfir, gypy, kapyr, etc., by adding to cow's milk a kind of mushroom that is found in those high regions near the snow-line. This *champignon* is found in the form of irregular, compact, elastic seeds, varying in size from five millimetres to five centimetres, whose surface is rough and wrinkled, something like the tops of cauliflower. In the dried state they are yellowish, break easily, and look a little like cartilage. They contain two bacilli, one of which is like the bayonet-shaped bacillus found in spontaneously-fermented milk; the other one has a little spore at each of its ends, and has been called *Dispora Caucasica* by Kern, of Moscow.

To prepare kéfir, the grains are first of all to be swollen up by putting them into warm water for five or six hours; then throw them into milk after carefully washing them, and this milk is to be renewed several times (two or three) a day. After a few days they will have become active and ready to use for making the kéfir drink, which is done as follows. Take a tablespoonful of the fermenting seeds to each pint of fresh milk, and keep the mixture at a temperature of 18° to 19° Centigrade, shaking it every hour. The next day the mixture will be found in a mass, when it should be filtered through muslin, to get rid of the grain and all the impurities that may be in it. It should then be bottled, and the bottles must not be filled quite full, as it will go on fermenting for some time in them; they should be well corked, and shaken from time to time. In twenty-four hours more it is ready for use, unless it is desired to have a kéfir richer in alcohol, when it should be left for two or three days longer. After four days the drink becomes too acid to use. Well prepared, it should be a thickish, cream-colored, frothy liquid. It is richer than koumyss in albuminoids, less alcoholic, and not so acid. As regards its use, the Russian doctors find its indication in all the anæmic states, where it is not a specific, but it is a good tonic aliment. In chronic anæmia a half-gramme of lactate of iron is added to each bottle. It has been found of great benefit in all the diseases of the digestive tube where there is atony. Dr. Lépine used it in ulcer of the stomach, and found his patients liked it better than milk, and that their gastric difficulties were relieved by it. Other patients, suffering with dilatation of the stomach and catarrh of the same organ, were improved. It was sometimes used alternately with good milk, when it was noticed that those who could not tolerate milk could use the kéfir with great advantage to them. It has been proposed lately to use some other ferment in place of the kéfir mushroom; but, so far as known, experiments have been without success. It may be asked, Why not be satisfied with pure milk? There are a number of answers to this which will occur to all who advise milk; then there is the motive that induced man to transform grape-juice into wine,—in a word, to introduce art into the preparation of his aliments.

Chondromata. — Cartilaginous tumors of

great size are not so common but what a short account of a recent clinic of Dr. Tillaux's at the Hôtel-Dieu may prove of interest, particularly as the patient presented a most curious example of this form of tumor. "The patient was about 40; his father at sixty-eight years of age is still alive, his mother had died suddenly at thirty-two, and of six brothers two had died young, one was suffering with phthisis, and the rest were quite well: so no antecedent history could be found for his affection. He had himself always been well, and never had had any other malady than these tumors. At the age of seven they began appearing on his fingers,—some thirty-three years ago. At first the index and middle fingers were enlarged only, and that was all there was to it; no pain was experienced, so but little trouble was taken about it. Little by little they increased in volume as the years went by, until when he was presented they measured seventeen to eighteen centimetres long and had a circumference of twenty-five to twenty-six centimetres; but their first character of indolence had never changed. He was only bothered with their enormous size, which prevented him from using his hands as he liked. The two index fingers were the only ones attacked, and the tumefaction was exactly limited by the metacarpo-phalangeal articulation, not extending a line beyond. A few years afterwards the second and third toes on the same side (left) were attacked, but they never got to the size of the fingers, being at present about the size of small eggs.

"Finally we come to the knee-tumor, which is the one for which he asks relief. It is of more recent date than those just referred to. Three years ago it did not exist, for he was treated for sciatica about that time on his complaining of pain and slight swelling about the head of the fibula. To-day you see a tumor there as large as a man's head, measuring sixty-five centimetres around its largest part: it is immobile, and has constantly been the seat of pain. Its consistence is soft in places, and the skin is drawn tight, but it is ulcerated in several places. The diagnosis as to the fingers and toes need not take long. They are typical chondromata: everything goes to prove that. They are round, hard, indolent, nodulated, and not the slightest pain in them, only differing from the usual forms of chondromata by their immense size.

"These tumors can develop themselves in soft parts, such as the parotid gland and the testicles, but they show themselves most frequently about the bones of the hand and foot. They are composed of cartilaginous tissue, though, curious to say, they *never* arise from the pre-existing articular cartilages. Not only is this so, but they also always respect the cartilages; and one can see in this patient that the articulating cartilages remain in good condition, notwithstanding the immediate neighborhood of these tumors. As to the knee-tumor, it cannot be quite the same kind, as it is soft, painful, and rapid in growth, and seems to come from the bone: yet it must be some relation to the others. Can it be that these tumors, which are always considered of the benign class, can take on a malignant character like carcinoma and sarcoma? According to what is called the neoplastic diathesis, it would seem so. This enchondroma is like what Virchow calls osteoid-chondroma, and according to him they often present a high degree of malignancy. The rule is adopted by most surgeons to amputate all the bone on which such tumors grow."

Dr. Tillaux amputated the left leg and the two fingers at the same time; the last weighed over three and a half pounds. On microscopic examination by Professor Cornil, they were found to be pure chondromata, and the knee-tumor was a chondro-myxoma, with predominance of the myxoma tissue.

Spasmodic Vomiting, Catarrh of the Uterus, Anæmia.—M. Victor Audhoui, who is Médecin de l'Hôpital de la Pitié (and one of the principal physicians at Vichy during the season), recently commented clinically on the above complex state which is so common in women in all countries. The doctor says, "The pathological theory is easy enough to formulate in this state, whether one considers the above three elements as constituting a disease or as depending as symptoms upon one single affection,—for instance, a simple general weakness,—or upon some lesion of the kidneys that has brought about autogenic poisoning which we call uræmia, etc., or else this state has supervened upon some one of the great number of habitual indigestions represented by dyspepsia. Whether you attach it to any of these states or consider it as an initial disorder, it can be best treated in the following manner:

"After having rectified as well as you can the régime of their lives, and having tried to re-establish the relations that ought to exist between the great functions by means that are appropriate to each individual case (the characters of which I cannot give in this rapid view), you must, above all, sustain and force absorption by the digestion of food. But ordinary aliments, even of the best, and that most desired by these patients, will not be tolerated. So you must give, as the only nourishment to be taken, pure milk with one-third of lime-water in it; and in order to prevent the constipation which is so constant with this medical aliment, you must have them take an injection of warm water every day on rising. This can be rendered laxative if needed. Besides this we may prescribe the following remedies:

"1. The patient is to take at night, on going to bed, first one and afterwards two of the following pills:

℞ Extract. nucis vomicæ, 1 Grm.;
Extract. belladonnæ alc.,
Extract. opii, āā 0.20 Grm. M.
F.—Divide into twenty pills.

"2. Twice a day (in the morning about eleven o'clock, and in the evening about seven) she should take, in a little water, thirty to forty drops of the tinctura ferri et potassii tartras, according to the last French Codex."

(It may be stated here that this preparation of iron is the one used by French physicians, Professor Germain Sée, and others, in anæmia and chlorosis, as it does not constipate.)

"3. The patient should give herself an injection (vaginal) morning and evening, as follows:

℞ Matricariæ, 20 Grm.;
Aquæ bullientis, 1000 Grm. M.

"The matricaria flowers are something like chamomile flowers, and they are to be allowed to infuse in the boiling water for an hour, and then strained and a few drops of cologne-water added to it on using it: it should be still warm when used.

"4. Lastly, it is useful to order a bath once a week, in which some aromatic alkaline salt should be dissolved,—like this, for instance:

Bicarbonate of soda, 250 Grm.;
Oils of lavender and mint, āā 1 Grm. M.

"I recommend practitioners not to confound this common state with dilation of the stomach. The trouble is that they undertake on very slight provocation to use washing out of the stomach, and strangely abuse it. It is extremely rare that this is needed. It is really only indicated when the stomach-contents are purulent; and I can assure you, in an extended practice in Paris and Vichy with gastric diseases, that this condition is extremely uncommon, so much so that in several hundreds of such cases I have used a stomach-sound in only three cases. In fact, I consider that style of therapeutics not only ridiculous when carried to extremes, but positively dangerous." THOMAS LINN, M.D.

PARIS, February 1, 1887.

PROCEEDINGS OF SOCIETIES.

JOINT MEETING OF THE PHILADELPHIA NEUROLOGICAL SOCIETY AND PHILADELPHIA MEDICAL JURISPRUDENCE SOCIETY.

JANUARY 24, 1887.

(Continued from page 362.)

JOHN A. CLARK, ESQ., then read a communication entitled

THE CARE OF PATIENTS OF DOUBTFUL MENTAL STATE, AND THE PRIVATE TREATMENT OF THE INSANE. (See *ante*, page 342.)

DISCUSSION.

G. W. BIDDLE, ESQ.: The papers that have been read this evening deal measurably with a subject of stupendous interest to all civilized communities; for it may be said, without fear of contradiction, that the disease of mental alienation is one which may involve any circle and any family; and it is therefore matter of satisfaction to the members of the two Societies which meet here to-night in joint convention that the subject which seems to be propounded for discussion touches us all so nearly. We must approach this subject with a good deal of calmness, and, as far as possible, with freedom from partisanship.

The tone of both of the papers that have been read is admirable. Two prominent topics seem to suggest themselves to us for consideration after hearing them: first, what are the conditions under which a patient shall be received for hospital treatment?—what are the guards which the law throws around the unhappy subject of this treatment to protect him in all his rights, so that he shall not be dragged from his friends, his business, and his home without a due regard to those rights? And, secondly, what is the best mode of treatment after he shall have become the subject of hospital treatment? I desire to say a very few words on each branch of this general subject.

I wish to say, in the start, that we must not believe that we have reached perfectibility. It is hardly a century since the unhappy subject of hospital treatment was treated as a malefactor of the worst grade, chained down and subjected to every personal indignity, and if not completely mad when he entered the institution, certainly made so by the treatment pursued. It is a subject of congratulation to us as Pennsylvanians that the first attempt at humane and rational treatment was begun in this State, and has been steadily advancing until the most prominent institution in this county and State has gone as far as perhaps it is possible to go for the relief of the sufferings of those who are incurably insane. But there is a very large class who are hovering on the border-line.

For the past twenty-five years I have watched with some care the enactments on this subject. Formerly the statement of any relative, with the certificate of any physician (not required to be verified by oath), was sufficient for admission into a hospital for the insane. There were grave objections to this. The reader of the first paper has said that Lord Shaftesbury asserted that out of one hundred thousand cases he had never known a man or a woman introduced as the subject of hospital treatment who was not a proper subject for such treatment. I see just opposite me a gentleman who will verify all that I say when I state that, fifteen or sixteen years ago, a man as sane as any one in this room was sent to an insane asylum on a physician's certificate. He was promptly discharged by a late chief justice on a writ of habeas corpus. He was, to use a euphemistic expression, the

victim of the hallucinations of his family: he was under no hallucination. These cases do occur, although they are undoubtedly rare. I think that it was in consequence of this occurrence that the Act of Assembly was passed requiring the certificate of two physicians to be made within a week after a personal examination, the examinations to be made separately and verified by affidavit before a magistrate of the county. There is nothing to exclude a joint examination. The object of the law was to throw each of these gentlemen on his own responsibility by requiring his separate affidavit; and surely no objection should be made to that. I know of no instance in which a physician has been brought in jeopardy of his pocket by making a certificate in good faith. It is possible, indeed probable, that there are such cases with which I am not familiar, but I doubt if they often occur. The certificate is in the nature of a privileged communication, and, if made in good faith, the provisions of the Act of 1883 should protect him if he has unfortunately fallen into error. He has done the best he could, and that is all that any one can do. Everybody makes errors of judgment every day of his life. I do not know, as at present advised, that we can go much farther in this direction. The medical profession has always been the pioneer in works of beneficence. A distinguished judge once said publicly that physicians did more good charitable work without expecting or receiving any earthly reward than any other body of men that he had ever met. The black sheep among them constitute but a small percentage. We must rather look, therefore, to the medical profession for improvement in this respect. The legislators of the State and the legal profession are always glad to receive suggestions from it. The law at present may be somewhat crude, but it is the best that has been suggested.

I may say in quasi reply to my distinguished friend on the opposite side of the room, that the person whom he followed to the gallows was convicted as properly under the laws as it is possible for a man to be convicted. The man may have been insane; such a thing is possible; but I believe that he was as properly convicted as a man can be under our very imperfect system of trial. We cannot look into the heart. We can only judge of the heart by the actions. Eighteen months ago there was something like an array in this room of the two professions against each other upon this point, which should not be. They should work together in all these subjects, and endeavor to pull in perfect harmony towards the desired end, and not be placed in antagonistic positions.

A word as to what the treatment should be after a patient is received. In addressing the eminent gentlemen here to-night, and the chairman, who is himself an expert of the highest order of merit, I wish to make some suggestions which have occurred to me some time since. I believe that there is a large class of the insane who have no homicidal or suicidal tendencies, who could be allowed a greater measure of liberty than they have at present under our imperfect system. I wholly agree with the suggestions of my friend Mr. Clark. There are undoubtedly a large number of men who may be of sound mind so far as the ordinary affairs of life are concerned, and who yet may be hovering on the border-line, and for whom residence in a hospital for the insane may be the worst possible treatment. If they could be separated from contact with associations which may be irritatingly exciting, and yet not be consigned to a hospital for the insane, but to some intermediate place of treatment, I believe that it would be a great gain. It is said, and I believe on the very best authority, that in order that there may be a good chance of a cure the disease must be taken in charge very early. The statistics with which we were favored to-night show that the cases treated within from three to six months of the access stand a vastly better chance of recovery than those taken after the first year. If the suggestions of Mr. Clark were carried out, I believe that they would do much good. I go so far as to say that I believe that even in the case of the incurable insane much of the restraint could be removed. The only dangers to be guarded against are danger of the individual to himself and danger to others. We should protect society, and we should protect the party against his own acts; but we are not required to go beyond this.

These are the thoughts passing through my mind after hearing the excellent papers that have been read. I am not a partisan or extremist on either side. So far as the law is concerned, I am willing to admit that it is a very rough instrument, and only approximates—and that very imperfectly—to the dispensation of justice in human affairs. Medicine is a science,—at least it is an art based upon scientific requirements,—and has a much higher field than the law. I believe that all these great improvements come quite as much from the medical profession, if not more so, than from any other quarter, and I am looking for further advance from the eminent men in that profession.

Dr. E. N. Brush: The objection made by Dr. Wood that there seems to be no provision by which a person dangerous to himself and to society can be placed in an asylum, except by the action of the friends, would seem to be met by the requirements of the lunacy statutes of the State of New York, which provide that a justice of the court may, upon complaint, issue a warrant and summarily commit a person who is complained of by any one as being dangerous to himself or to others, upon taking proof as to his insanity. If his friends are not able to support him, the charges

are collected from the county; otherwise his friends or estate must bear the expense.

In regard to the accountability of physicians, I think that they are not anxious to shift any of the responsibility which devolves upon them for careless or injudicious opinion; still the fact remains that there is nothing to prevent a lunatic discharged unrecovered from bringing action for damages, which, although unsuccessful, may put the physician to much expense in defending himself.

I am happy to be so well supported in my plea for early treatment as I have been by Mr. Clark's paper. His suggestion for intermediate hospitals is in the line of early and prompt treatment.

I see no reason, however, why the suggestions of Mr. Clark might not be applied to many of the asylums of this State. I am satisfied that there is no superintendent or physician connected with any asylum, if the cases were brought early, who would not be willing to place the patients in such a position that their recovery would be hastened and not retarded by unpleasant surroundings.

At the hospital with which I have the honor of being connected, the Pennsylvania Hospital for the Insane, we every year treat a number of these incipient cases, who come and remain voluntarily, and who do not seem in any way disturbed by their surroundings, and we know of no legal objection to their remaining for indefinite periods, as long as no detention is exercised. As far as a patient's residence in an intermediate hospital is concerned, there must be some legal right to detain him there in case he will not yield to the judgment of his friends or the physician, otherwise we are left in the same position as at present.

Dr. S. Weir Mitchell: Eight or nine years ago, after returning from England, where I had been through many of the hospitals for convalescents attached to the great English hospitals in which patients of a doubtful mental state were placed, I went to the authorities of the Pennsylvania Hospital for the Insane and proposed, for myself and a lady of this city, to make a reasonably liberal gift for four years if they would start an institution of this kind. It was promptly rejected as not practicable. The offer was then made to the managers of the Friends' Asylum, but after consideration it was rejected. I am happy to learn that, under the guidance of my friend Dr. John C. Hall, better counsels have prevailed, and the first institution of this kind has been established near this State. I believe that there is a similar institution in New York State.

Dr. H. C. Wood: I should like to say a word with reference to the remarks of my friend Mr. Biddle, referring back to the old Taylor case. It seems impossible to get the legal mind to understand the position which I and, I believe, most of the medical gentlemen connected with that case took. I never said that the laws of the State of Pennsylvania in that case were not properly executed. I do believe that the laws of the State of Pennsylvania need alteration. The difficulty is that the legal gentleman who administers the law makes the law as it exists a part of himself, and then becomes a partisan of the law as it now exists. The legal profession come to believe that the law is perfect, and the moment any one dares to differ in that respect, that moment the elements of more or less partisan feeling make their appearance.

Dr. William L. Robinson: There is one class of patients to which reference has not been made, and that is the criminal insane. I should like to know what disposition should be made of these people at the end of their sentence. If they are liberated, they are soon arrested for repeated crimes and returned to prison. We have already received this year at the penitentiary six insane people liberated in November last. The expense of the repeated trials of these people is great. There should be some method of disposing of them which would avoid this expense and at the same time protect the community. Our asylums for the insane have not detained them when sent there. Will some of the chiefs of asylums present tell us of the influence of the criminal on other insane patients?

Dr. John C. Hall: I feel that I can speak somewhat experimentally, as the Friends' Asylum has tried this intermediate system of treatment, as Mr. Clark has termed it. Our house at Atlantic City has given good results. There are many cases that can be better treated in a small house than in the wards of a large hospital. There are many persons whose relatives would send them to such a house, and yet would not place them in a hospital merely because of the prejudices which exist in reference to these institutions. I should be glad if some modification in the lunacy laws could be made to cover this particular point. It is, I think, a subject of vital importance.

Dr. Francis X. Dercum: I think that the point raised by Dr. Wood has not been sufficiently dwelt upon,—that is, in regard to the protection of the community from the insane who are not confined by their friends. A year ago I had an experience illustrating this very point. I was called in the middle of the night to a house in my neighborhood, where I found a woman in a state of acute mania. She had torn off all her clothing, and was engaged in a desperate struggle with her father and two sisters. The latter soon became terror-stricken. I alone was unable to control her, and we were obliged to call in assistance from the street, and we had the unedifying spectacle of a strange man, a policeman, and a physician in a struggle with a naked woman on the floor. The patient was finally quieted by the hypodermic use of

sedatives. The next morning I called at the house with the object of arranging for her removal to an asylum. I was met with a prompt refusal. In my ignorance of the law I went to the police-station and informed the sergeant of the facts of the case, and there the matter ended.

Dr. CHARLES K. MILLS read a paper entitled

SUGGESTIONS AS TO LUNACY AND INEBRIATE LAWS.

DISCUSSION.

Dr. S. WEIR MITCHELL: With reference to voluntary incarceration, I wish to say that I was one of the Commission that framed the law of 1883. I made great efforts to have this period of one week changed. I desired that it should be made at the will of the person concerned, but limited to six months. I was, however, unable to bring a majority of the Commission to this view.

Dr. S. PRESTON JONES: I have made some inquiry in reference to this law of Connecticut, but I do not find that it has been resorted to to any extent. At the Retreat at Hartford they have received only one patient in ten years, under its provisions. There is only one inebriate asylum in the State, and that is a private one. The law was amended two years ago, so as to permit a judge of probate to put the inebriate under the care of any reputable physician in the State. There is a law in this State providing for the care of the property of a drunkard, but it is rarely resorted to.

GEORGE W. BIDDLE, ESQ.: I wish to express my concurrence with Dr. Mitchell in regard to the desirability of extending the period to which a man may voluntarily commit himself. This is reasonable to the last degree. I should have gone a little further, and have said any time within one year if the patient choose.

Dr. CHARLES K. MILLS read a paper on "Confessions of the Insane," and related the case of a patient who confessed (about the same time that Wilson made his confession) to having murdered a man named Stahl and to having thrown his mutilated body into Wissahickon Creek.

The next paper was entitled "Description of the Brain of John M. Wilson, recently Hanged at Norristown, Pennsylvania," read by Francis X. Dercum, M.D. (See page 368.)

(To be continued.)

PHILADELPHIA ACADEMY OF SURGERY.

MEETING OF FEBRUARY 7, 1887.

(Continued from page 359.)

DR. CHARLES W. DULLES: I have long been interested in the study of hydrophobia, and it is but natural that I should be much interested in the paper of Dr. Ernst. He has described more accurately than I have seen described by any other experimenter the experiments which he has made with reference to this subject. I think I may say that I am familiar with everything that M. Pasteur has said or written upon this subject since he began his investigations, and it is a curious coincidence that my own studies began at exactly the same time. I have failed, as have other investigators, to find in the reports of M. Pasteur's experiments that detail and that accuracy which would become the seriousness of the subject which he has undertaken.

The experiments so accurately described by Dr. Ernst prove certain things conclusively, but I am, in some respects, sorry to say that I am not entirely convinced that they prove conclusively what he thinks they prove. This for several reasons.

In the first place, I think that a fundamental error is connected with the material with which he experimented and which he received at the hands of M. Pasteur, namely, two rabbits, one of which died on the voyage and the other survived. Those who are familiar with M. Pasteur's work are aware that he considers that the most important characteristic of the refinement to which he has brought the virus of rabies is the fact that it produces the outbreak, and ordinarily death, in six or seven days. When M. Pasteur began his work he stated that the inoculation of the virus from mad dogs under the dura mater produced rabies in a period of two or three weeks. Any one can see that there is considerable difference between two weeks and three weeks. Of the two rabbits which Dr. Ernst received, one died in nine days and the other in thirteen days. M. Pasteur, in the last communication in which he speaks of this point, says that he now gets a regular period of incubation of seven days, and that there is a gradual tendency to diminish to six days. I am not disposed to take anything that M. Pasteur says too exactly. I have no hesitation in saying that M. Pasteur says very different things at different times, and I have sometimes found it extremely difficult to reconcile his statements. An illustration of this is seen in what we have heard to-night. We cannot presume that there is greater candor on the part of M. Pasteur than there has been on the part of Dr. Ernst, yet Dr. Ernst speaks of the average period of incubation in his rabbits which have died as being fourteen days, the shortest period being ten and the longest twenty-one days. Speaking of averages in so small a series of cases is entirely fallacious. In the cases reported, the period at which death has occurred has varied between ten and twenty-eight days. Ten days is three days more than M. Pasteur's average, and twenty-eight days is four times as great as Pasteur's period.

Another point in which I think that the speaker has fallen into error is in stating that

Pasteur commenced his work of inoculation with virus derived from a child dying of hydrophobia. Pasteur has repeatedly stated that his virus was originally derived from a dog. There was a child who died of what was supposed to be hydrophobia, and M. Pasteur made some experiments in connection with this child which were conspicuous in the fact that they led him into an egregious error. Dr. Ernst has spoken of Pasteur's virus protecting against itself and also against the bites of rabid dogs. If we grant M. Pasteur's claim that his inoculations have saved the lives of a number of persons bitten by dogs, it would have to be admitted that this was proved; but I do not admit this claim. As to animals, I suppose that Dr. Ernst refers to certain experiments made under the eyes of the government commission, in which certain dogs were inoculated. The report of these experiments was made at the International Congress at Copenhagen, the results of the experiments being telegraphed to Pasteur there. I have taken the trouble to investigate the work of this commission, and I find that there were only four cases which were traced to their end, and that none of these had any bearing upon the question under consideration. What we want is absolute proof that this method of Pasteur has anything to do as a protection against what is called hydrophobia.

I would call attention to another point. Dr. Ernst has reported a number of failures in his experiments, but I have failed to see any admission on the part of M. Pasteur that any of his experiments have been failures, although he has recently admitted that there must be some failures with every method. It seems curious that Pasteur is the only person who has made these experiments who has not met with a large proportion of failures.

Dr. Ernst has referred to Spitzka's experiments. I had the pleasure of seeing some of the animals he experimented upon, and I am convinced that they presented symptoms described by M. Pasteur as characteristic of the inoculation of rabies.

The control experiments of Dr. Ernst are very interesting, and, so far as they have gone, very instructive. What we need to settle the question whether or not this virus can be called specific is a series of subdural inoculations made, after the method of Pasteur, with a variety of substances. The control inoculations which Dr. Ernst has made were, I believe, made in the groin, and not under the dura mater, as is done in the so-called rabic inoculation.

To certain of Dr. Ernst's conclusions I think we may all agree. It would be foolish to deny that M. Pasteur has obtained something, which we may call a virus, which being inoculated produces a certain set of symptoms, and that when a similar material attenuated in a certain way is inoculated into animals to prepare them for subsequent stronger inoculations they will resist the action of the stronger inoculations. Of this there can be no doubt. But the idea that Pasteur can prepare a virus of greater intensity, which, being inoculated after the accidental inoculation of another virus of the same kind, will catch up to it and pass beyond it in the period of incubation, and that these two will produce no effect when either would have produced death, staggers my intelligence. It may be true, but I can see nothing logical in it.

Everything in this work depends upon attention to details. Dr. Ernst has told us that in order to make these protective inoculations it was necessary to have the material ready upon certain given days. I should like to know how it would be possible to have the virus ready on any given day, when the animal may die at any period from three or ten days to twenty-eight days. I think that the way in which this is overcome in Paris is this: in Pasteur's laboratory it is assumed that the operation has been a success, and when the day arrives when the virus is needed the animal is killed. When we remember what proportion of failures occurred in Dr. Ernst's experiments, what guarantee have we that the animals which are supposed to be preparing the virus are not those which if not killed would have escaped?

To my mind, the essential point in this matter is simply this: that this interesting subject which has been so ably investigated has nothing to do with rabies at all. I am confident from my own studies that Pasteur's work has nothing to do with rabies. I should like to know exactly what Pasteur began with. If there is any living man that can tell that, it is Pasteur; but he has not told it. The nearest I can get at this is the inference that M. Pasteur is working with the descendants, through a great series of generations, of some material which he obtained from a dog in the pound at Paris. I am convinced that his first virus was not obtained from the child spoken of before. From the beginning to the end it has been assumed that this is the virus. This is, I think, entirely erroneous.

A word with regard to the symptoms of the paralytic form of rabies and the admission of Dr. Shakespeare with reference to what he saw in Koch's laboratory. In recent investigations in Germany with reference to the tetanus-germs, it has been found that some of the symptoms produced are similar to those of Pasteur's artificial rabies. It is interesting to note that the virus for this tetanus is not necessarily derived from an animal that has died of tetanus, but that it may be obtained from garden-soil. The accounts of a good many of the cases supposed to have died of rabies would warrant the belief that they have died of tetanus. I have already stated my objections to M. Pasteur's claims and assumptions, in a paper read before the Philadelphia County Medical Society a year ago. In a matter like

this, where opinions are so diametrically opposed, time must decide who is right and who is wrong; but for myself I have no hesitation in saying that I think that Pasteur's work will prove before long to have been a delusion and a snare, and that the sooner we get back to legitimate methods of clinical study the sooner will we understand the whole subject of hydrophobia and rabies.

Dr. Charles B. Nancrede: Since one gentleman has been arguing solely by analogy without any experimental knowledge of the subject, I would like in answer to submit two or three questions, without committing myself to Pasteur's or any other theory. Will any gentleman here affirm that vaccination will show an exact period of incubation in every case? Will any one say that he has not seen it anticipate or defer for a period of days? Is it not true that tetanus may kill, as in the classical case, in fifteen minutes, but may not cause death for weeks? Yet does any one doubt that it is the same disease? We have a right to average the probable number of hours or days that a case of acute, subacute, or chronic tetanus may continue. I have no doubt that there are cases of acute, subacute, and chronic rabies. I would like further to add that, twenty years ago, the results of antiseptic surgery were denied because the theory was thought to be unproved. Now most of us, whether we believe in the theory or not, do not deny the results. Would it not be just as well to hold in suspense our judgment with reference to this matter, and not condemn it simply because the theories do not fit in with our preconceived ideas, especially if we have had no personal experience in experimental work?

The challenge has been thrown down for a known instance where a weaker virus could overtake a stronger virus and prevent its action. We are constantly putting this in practice in the case of smallpox. I, in common with most here, have seen it myself, and Dr. Welch has stated over and over again that unprotected children that have been sent to the smallpox hospital with their parents have been successfully vaccinated and have never contracted the disease.

Dr. R. S. Huidekoper: My experience with hydrophobia is confined entirely to inoculations made for the purpose of confirming a clinical diagnosis. There is one point in regard to the symptoms of hydrophobia to which I will refer. The word "furious" should be used with the word "form," and the word "excitable" with the word "stage." During the course of mute hydrophobia, which commences with paralytic symptoms, we have certain stages of hyperæsthesia or perversion of the sensitive nerves, especially the nerves of special sense. This may last a considerable time. The paralysis of certain groups of muscles appears after the stage of hyperæsthesia. Another form of hydrophobia is that known as the furious form. These two forms are influenced to a great extent by the species of the animal and by the individuality of the animal. In rabbits the usual form is the mute or paralytic form. In man both forms are seen. In the horse of both sexes and in male cattle the furious form is the most common. In female and younger cattle the paralytic form is usually met with. In dogs both forms occur, influenced by the race. In the ruder races and in those in which there is a reversion to the lower type the furious form is met with, while in those races which have been more domesticated, as the setter, the spaniel, and the poodle, the paralytic form is the more common. In certain animals, as, for instance, the rabbit, the furious form can be looked upon as merely an idiosyncrasy of the individual. Only a general idea could be formed beforehand as to the form the disease would take in any given dog.

As to the period of incubation, I think Dr. Dulles has entirely misunderstood Dr. Ernst's paper. I think Dr. Ernst put special cases which have shown a greater or less period of incubation to one side, and has based his statistics upon the larger number of cases which ran an even course. The period of incubation is excessively variable when the inoculation is directly under the dura mater. It is certainly longer when the contagion is taken in the ordinary way. There is one case in which the disease did not develop until seven and one-half months after inoculation. During this time the animal was entirely secreted from the possibility of any contagion, and all the time it was under my own observation.

Dr. Shakespeare has called attention to the fact that his average period is twenty-four hours longer than that of Pasteur. I did not note whether he stated the number of generations that the hydrophobic virus had been through in his cases. Pasteur's is based upon twenty-two inoculations of rabbits before the absolute fixity of the virus was obtained.

(To be continued.)

NEW YORK PATHOLOGICAL SOCIETY.

A STATED meeting was held February 9, 1887, the President, T. MITCHELL PRUDDEN, M.D., in the chair.

ON STAINING ELASTIC FIBRES.

Dr. FREEBORN described and presented microscopical sections illustrating two new methods of staining elastic fibres, one known as Lustgarten's method, and the other as Herxheimer's.

PARAPLEGIA OF POTT'S DISEASE.

Dr. RIDLON presented a portion of the spinal cord of a girl, 6 years of age, who had suffered about five years with a kyphosis in the upper dorsal region of the spine. She was first seen by Dr. Ridlon in 1883; the kyphosis

had been observed in 1881. The treatment at St. Luke's was rest in bed. The paralysis of the lower extremities became complete; she did not lose control over the bladder and rectum. In 1886 she began slowly to regain some control of the muscles of the leg, and was finally able to walk across the ward, wearing a support. Bronchial and pulmonary symptoms developed, and she died recently. Dr. Frank Ferguson, who made the autopsy, found old adhesions over both lungs, tubercles, and areas of hemorrhage of small size. The left ventricle was moderately dilated, the right enormously dilated. The caries of the spine involved the last cervical and the first five dorsal vertebræ; the sixth cervical and the sixth dorsal vertebræ were not more than an inch and a half apart; the space between was filled with cheesy material. The cord at this region was flattened, and the gray substance not distinguishable; above and below the angle of deformity it appeared normal.

Dr. Ridlon knew not why some cases of paraplegia from Pott's disease recovered within three months, while others required more than that number of years. He knew of no treatment of particular benefit, except absolute rest in bed. He had tried iodide of potassium, and felt convinced that it was of no value except in syphilitic cases. Dr. Ferguson had seen several cases of Pott's disease of the upper part of the spinal column, accompanied with dilatation of the right side of the heart and consequent pulmonary symptoms, terminating life.

Dr. Van Santvoord related the case of a girl who recovered from paraplegia attending a kyphosis in the dorsal region after application of the actual cautery over the deformity, and Dr. Carpenter referred to the case of a man who recovered so far as to be able to walk about and do some business after having suffered from paralysis of the lower limbs three or four years. He had arranged an apparatus for partial suspension when in bed.

Dr. Ira Van Gieson suggested that the recovery of motor power took place through collateral tracts.

Dr. Ridlon thought that about nine cases out of ten of paraplegia from caries of the spine recovered, but he was unable to tell why these recovered and why the remaining one-tenth did not.

MENINGITIS OCCURRING IN THE COURSE OF PHTHISIS.

Dr. H. J. Boldt presented the lungs of a child, 9 months old, which had been apparently in perfect health until about four days before death, when unmistakable symptoms of meningitis developed. There had been no symptoms to call attention to the lungs, yet at the autopsy there was found adherent pleura and a cavity containing pus, surrounded by fibroid tissue. The brain showed simple meningitis.

OVARIAN CYST; PERIUTERINE INFLAMMATION.

Dr. Boldt also presented the uterus and appendages removed at autopsy from a woman, aged 49, in whom a small ovarian cyst had been diagnosticated and an operation had been advised but rejected. The uterine extremities of the tubes were closed, the ovary on the right side was cystic, the ovary and tube on the left side were indistinguishable in an inflammatory mass; among the retroperitoneal glands were small tumors, probably sarcomatous. The case he thought emphasized the importance of an immediate operation in such cases of pelvic tumor, although of small size.

ANTHRACOTIC PNEUMONIA.

Dr. W. H. Porter presented a pair of lungs which illustrated a class of cases a number of which he had seen this winter. The patients entered the hospital with the history of having worked under ground, having had chill, followed by a rise of temperature, which, as a rule, did not go above 103° or 104° F. They got along pretty well the first week; the temperature then fell, and the symptoms abated; they felt pretty comfortable until persistent dyspnœa made its appearance, and most of them died of the dyspnœa and œdema of the lungs. Whether the anthracotic condition of the lung predisposed to the lobar pneumonia he was unable to say. In the specimen presented, the pigmentation was very deep.

DILATED URETERS.

Dr. Thatcher presented a ureter found dilated from the presence of small polypi developed from the lining membrane. He also presented the ureter found in a fœtus of 6 months, dilated to the size of the thigh.

FOREIGN BODY IN THE EYE.

Dr. Ira Van Gieson presented the specimen, showing a thorn which had penetrated the sclera one centimetre posterior to the sclero-corneal junction, passing through the globe as far as the diagonally opposite ciliary body. Enucleation had been performed three weeks after the accident. Panophthalmitis was present.

TUBERCULAR DISEASE OF THE PHARYNX.

Dr. Van Santvoord presented the pharynx of a child which for some time had suffered from symptoms of pulmonary tuberculosis. A few days before death dysphagia developed, but the house-physician failed to discover any cause within the pharynx. The autopsy showed one large ulcer in the pharynx, one or more smaller ones, and changes in the lungs. Dr. Van Santvoord thought that tubercular pharyngitis was probably less rare than would be inferred from the books: the pharynx being seldom examined, disease there might be overlooked.

VAGINAL HYSTERECTOMY, UTERINE FIBROMA, AND POLYPI.

Dr. DUDLEY presented the uterus removed by the vagina in a woman, aged 48 years, suffering with carcinoma. She was the mother of eight children, had been attended by a midwife, and was unaware of a laceration of the cervix which was present. After cutting through the cul-de-sac a small fibroid of the uterus was found, and he was obliged, after passing the elastic ligature around the uterus, to remove it piecemeal. This method of operating necessitated the use of the ether three hours. The patient rallied well, but the next day suppression of urine existed, which caused death thirty-eight hours after the operation.

Dr. Dudley also presented a sloughing fibroid removed from the interior of the uterus, which had given rise to hemorrhage and pain. This patient had an intermittent heart-beat and also an aortic murmur; there was also albumen in the urine, which disappeared under the use of digitalis and potash. Notwithstanding the condition of the heart and urine, he gave ether. It was given a second time yesterday for closure of a double laceration of the cervix, and it would be given a third time for laceration of the perineum extending into the rectum. Comment upon the use of ether was left for Dr. W. H. Porter, who had made the microscopical examination of the first specimen.

Dr. Dudley presented a third specimen, it being a small polypus of the uterus, of interest from the fact that it was removed two years after the menopause, and at that time the uterus was found not diminished in size, but rather enlarged; the cervix was small.

Dr. W. H. PORTER said the carcinomatous disease in the first specimen was of the mixed form. The wound made by the operation was absolutely free from suppurative process. The kidneys were in a very rapidly advancing stage of acute parenchymatous metamorphosis. He had during the past three years made twelve or fifteen post-mortem examinations after some severe surgical operation, the patients having developed symptoms ordinarily classed as septicæmic. Yet the post-mortem examination showed the wounds undergoing healthy reparative process, with nothing to point to suppuration. In most of the cases the urine had been examined prior to the operation, and, as a rule, albumen and casts were absent, but in all the urine (when any could be obtained) contained albumen and casts after the operation. The kidneys were found in a state of advanced acute parenchymatous change, the tubules being blocked with casts. The so-called septicæmic symptoms were truly uræmic in nature. Etherization cut off oxygen from the system, which became poisoned with carbonic acid and the excessive amount of effete material, while at the same time there was decreased nutrition and physiological action of the different organs, particularly of the kidneys, which became surcharged with the waste and poisonous productions. He thought, therefore, that particular attention should be given to keep up the normal function of the kidneys before and after operations demanding an anæsthetic, and the anæsthetic should be given in as small quantity as possible. He believed that the larger the quantity of any anæsthetic the more injurious the effects. Ether also had a destructive effect upon the red blood-globules, more so than chloroform.

Dr. BOLDT had during the past year seen three deaths from so-called septic symptoms after operations, but the autopsy showed no septic centres, whereas the disease in the kidneys was sufficient to account for the fatal result.

Dr. DUDLEY said that he was now in the habit of giving about half a grain of morphine hypodermically half an hour before operating, which did away with the necessity for giving so much ether and at the same time diminished shock.

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting of the Academy was held February 3, 1887, the President, ABRAHAM JACOBI, M.D., in the chair.

The PRESIDENT, in an interesting address, pointed out graphically the usefulness of the Academy with its Sections, and referred to the necessity of soon purchasing a new building-site.

ON DETECTING AND LOCATING METALLIC MASSES IN THE HUMAN BODY BY THE INDUCTION BALANCE AND THE TELEPHONIC PROBE.

Dr. JOHN H. GIRDNER, the author, first referred to the apparatus constructed by Professor Bell for detecting the bullet in President Garfield's case, an experiment which failed because of the haste in its preparation, and because the patient was lying upon a metallic mattress, unknown at the time, which interfered with the proper working of the instrument. Dr. Girdner said that now, however, we have a perfected apparatus, which will detect and locate any piece of metal wherever situated in the human body. It would prove particularly useful in times of war. The second apparatus, which he ventured to name the telephonic probe, was also the invention of Professor Bell, and was useful in connection with the induction balance, as by it the exact distance to the ball could be determined.

In the construction of the induction balance a bichromic battery was used, with six cells and an ordinary interrupter, the interruptions being about six hundred to the sec-

ond. The exploring cells were put in a framework of wood, which he called the explorer, while to the others the name adjusting coils was given. Thus in the primary current were two coils, in the secondary current were also two coils, and in the circuit was a telephonic receiver. When the exploring coil was not in relation to a metallic substance, there was silence in the telephonic receiver; but as the explorer approached or receded from the metallic mass the balance was disturbed, producing a musical tone in the telephonic receiver. The sound was distinct a distance of six inches from the metal if located in the human body; a less distance if the intervening space was occupied by air or an inorganic substance.

The telephonic probe consisted of a telephonic receiver and two wires, one terminating in a long, slender steel probe, and the other being connected with a steel plate laid over the surface of the body in the neighborhood of the metallic mass, as determined by the induction balance. The steel probe being now plunged into the body (the surface having been first rendered insensitive by an anæsthetic), as soon as it reached the metal a distinct click was heard. The practical working of the first instrument was demonstrated upon a man in whose chest a bullet had become lodged during the rebellion, and of the second upon a piece of beef into which a mass of lead had been placed.

Dr. NEWTON M. SHAFFER read a paper on

THE USE OF CONTRACTION IN THE TREATMENT OF CLUB-FOOT, WITH A CONSIDERATION OF SOME OF THE MECHANICAL PRINCIPLES INVOLVED, AND A DESCRIPTION OF THE ANTERO-POSTERIOR AND LATERAL TRACTION APPARATUS.

The paper was supplementary of one previously published in the *Medical Record*. Numerous diagrams were presented, showing the mechanical principles involved in motion at the ankle-joint in health, and it was a return to this state for which treatment was instituted in club-foot. The author claimed that there was only one antero-posterior centre of rotation, and that was not at the ankle-joint, but below it. The direction of the heel in flexion of the foot was downward and forward, and of the toes forward and upward. These principles should be carried out in any apparatus designed to overcome club-foot. But in fact the apparatuses employed ordinarily act on principles quite opposed to those which we see in nature. For instance, instead of being constructed and applied in a manner to push the heel downward and forward and to bring the toes upward and forward in overcoming talipes equinus, they make direct traction upon the toes, fix the heel in a manner to prevent it going downward and forward, and indeed, by the force exerted upon the toes, tend rather to bring the heel in the opposite direction,—namely, backward and upward. His own instrument, based upon the principles seen in the action of the healthy foot, was then described, and also the one intended to overcome equinovarus,—instruments which he had greatly improved since his last publication. He rarely found cases which did not conform to traction treatment, and still more rarely those which did not yield to tenotomy and traction combined.

Dr. RIDLON said that after six years' experience he was unable to obtain as good results from the lateral shoe as were obtained by Dr. Shaffer. There were certain cases in which good results could not be obtained by traction, by whomsoever applied, and he thought we ought to be able to distinguish those cases from the beginning. One indication was a shiver or shudder passing throughout the patient's system when the foot was placed upon the stretch.

Dr. KETCH said it ought not to be forgotten, in applying Dr. Shaffer's method of treatment, to employ traction intermittently. Relapses after tenotomy were common, and the usual, so-called, after-treatment was rendered much less by the use of traction with Dr. Shaffer's apparatus. He had been much gratified with the results of the lateral extension shoe.

Dr. JUDSON remarked that, inasmuch as Dr. Shaffer's apparatus was capable of exerting a great deal of force, he thought it should be in capable hands. He would say, but not as a stricture upon the paper, that proper treatment, instituted very early, ought to do away with the necessity for an operation or apparatus.

Dr. SHAFFER closed the discussion, and expressed some surprise that Dr. Ridlon had found the use of his lateral traction apparatus difficult. In fact, the parents could regulate it after a few visits by the physician. It should be made to fit in the first place, and the treatment should not be hastened. Some of his best results had been obtained in cases in which Dr. Ridlon thought tenotomy was indicated: namely, pain and a shudder passing through the system on making traction with the shoe.

The President was chosen as one of the committee to consider the question of an eligible building-site for the Academy, the other two, consisting of Drs. George A. Peters and F. A. Castle, having been named by the Council and Trustees.

In March the following resolution will be voted upon:

"*Resolved*, That the Trustees and Council be and are empowered to purchase a site or building, or erect a new building for the Academy, when such a course shall be considered expedient."

The Academy then adjourned.

REVIEWS AND BOOK NOTICES.

DISEASES OF THE DIGESTIVE ORGANS IN INFANCY AND CHILDHOOD. With Chapters on the Investigation of Disease and on the General Management of Children. By LOUIS STARR, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania, etc. With Colored Plate and other Illustrations. Philadelphia, P. Blakiston & Co., 1886.

The class of disorders which are included under the title of diseases of the digestive organs is so numerous and important as to warrant a separate treatise upon the subject. This is rendered necessary by the insufficient attention usually given in works on pediatrics to the general regimen, which is even of greater importance than the administration of drugs. Commencing with affections of the mouth, Dr. Starr systematically discusses the individual disorders which affect the alimentary tract. The recommendations for treatment are clear, full, and evidently based upon extended experience. The volume is handsomely printed.

A REFERENCE HAND-BOOK OF THE MEDICAL SCIENCES. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Illustrated by Chromo-Lithographs and Fine Wood Engravings. Edited by ALBERT H. BUCK, M.D., New York City. Volume IV. Bound in cloth, sheep, and half morocco; prices, $6, $7, and $8 per volume. New York, William Wood & Co.

Commencing with Ichthyol, the fourth volume of this valuable Reference Hand-Book carries the subjects, alphabetically considered, as far as Melford Springs. The most important articles are those on Insanity, on the Kidney, on Labor, on the Larynx, and on Micro-Organisms, which are freely illustrated. The technology of the culture-methods of the various forms of bacteria, pathogenic and other, is carefully described by a competent hand. For convenience of reference, clearness of statement, and presentation of the present state of development of the several medical sciences, we believe this work to be unrivalled.

MISCELLANY.

THE Medical Society of the State of New York held its eighty-first annual meeting in Albany, February 1, 2, and 3. An essay by Dr. A. N. Bell, of Brooklyn, entitled "Physiological Condition and Sanitary Requirements of School-Life and School-Houses," received the Merritt H. Cash prize, and was ordered to be printed and distributed to all municipal and other authorities and officials having schools under their management.

The newly-elected officers are—

President.—Dr. Alfred L. Loomis, of New York.

Vice-President.—Dr. A. M. Phelps, of Chateaugay.

Secretary.—Dr. William Manlius Smith, of Syracuse.

Treasurer.—Dr. Charles H. Porter, of Albany.

THE CAMDEN COUNTY MEDICAL SOCIETY held a meeting on February 8 at the West Jersey Hotel, when by invitation Dr. Thomas G. Morton gave a demonstration of the appliances and modes of dressing wounds antiseptically. A number of guests were present, for whom excellent entertainment was provided.

PROFESSOR LUDWIG BANDL enjoys the rare privilege of reading his own obituary notices. His sudden and severe illness soon after his arrival in Prague led to the premature publication in a German medical journal of his death. This announcement has also been made by a number of American journals, which now, with as much grace as possible, have to congratulate him upon his recovery.

OFFICIAL LIST

OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY FROM FEBRUARY 13, 1887, *TO FEBRUARY* 26, 1887.

LIEUTENANT-COLONEL JOSEPH R. SMITH, SURGEON.—Detailed, in addition to his present duties, as President of the Army Medical Board in New York City, New York. S. O. 38, A. G. O , February 15, 1887.

MAJOR W. S. TREMAINE, SURGEON.—Sick-leave still further extended four months, on surgeon's certificate of disability. S. O. 39, A. G. O., February 16, 1887.

CAPTAIN LOUIS J. TESSON, ASSISTANT-SURGEON.—Ordered for duty as attending surgeon at Headquarters Division of the Missouri and examiner of recruits at Chicago, Illinois. S. O. 44, A. G. O., February 24, 1887.

CAPTAIN ARTHUR W. TAYLOR, ASSISTANT-SURGEON.—Relieved from duty at Camp Medicine Butte, Wyoming, and ordered for duty at Fort Laramie, Wyoming. S. O. 14, Department of the Platte, February 12, 1887.

CAPTAIN M. C. WYETH, ASSISTANT-SURGEON.—Ordered from Fort Wayne, Michigan, to Fort Barrancas, Florida. S. O. 39, A. G. O., February 16, 1887.

CAPTAIN GEORGE MCCREERY, ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 35, A. G. O., February 11, 1887.

FIRST-LIEUTENANT CHARLES C. BARROWS, ASSISTANT-SURGEON.—Resignation accepted by the President, to take effect February 17, 1887. S. O. 42, A. G. O., February 19, 1887.

FIRST-LIEUTENANT WILLIAM J. WAKEMAN, ASSISTANT-SURGEON.—Relieved from duty in the Department of the Platte, to take effect on the expiration of his present leave of absence, and ordered for duty at Fort Walla Walla, Washington Territory. S. O. 36, A. G. O., February 12, 1887.

FIRST-LIEUTENANT CHARLES S. BLACK, ASSISTANT-SURGEON.—Ordered from Fort Clark, Texas, to Fort Davis, Texas. S. O. 23, Department of Texas, February 18, 1887.

FIRST-LIEUTENANT EDWARD R. MORRIS, ASSISTANT-SURGEON.—Leave of absence extended twenty days. S. O. 35, A. G. O., February 11, 1887.

FIRST-LIEUTENANT CHARLES F. MASON, ASSISTANT-SURGEON.—Resignation accepted by the President, to take effect March 25, 1887. S. O. 44, A. G. O., February 24, 1887.

PHILADELPHIA, MARCH 19, 1887.

ORIGINAL LECTURES.

CLINICAL LECTURE ON THE TREATMENT OF SYPHILIS.

Delivered at the Hôpital de la Pitié, Paris,

BY PROFESSOR VERNEUIL.

(Translated for the MEDICAL TIMES from advance sheets.)

IN 1867 I read a communication before the Société de Chirurgie in which I opposed the views of the partisans of the expectant treatment of syphilis. I held at that time that this affection should be treated as soon as the diagnosis was made out, or just as quickly as the primitive or secondary manifestations were perceived; and I also stated that I could not see any advantage in waiting. It is impossible to judge beforehand if the virus is going to develop in a weak, medium, or strong form, or if it will be transient or tenacious. I therefore commence the general treatment as soon as possible, making every effort to prevent tertiary syphilis. It is true that I am never sure that I have attained this end, for tertiary accidents are happily rare, and one can never tell if they will show themselves or not. But, without having the actual proof, I believe in the efficacy of preventive treatment by mercury in all these cases.

If I cannot support my statements with exact statistics,—which is difficult to do in any disease,—my experience is sufficient to enable me to express at least a most profound conviction that the full mercurial course is the best preventive of tertiary syphilis.

Expectation is useful for only one thing: that is, to show to the physician the natural evolution of this disease and its degree of gravity; but, on the other hand, it is open to the objection of losing precious time, during which the virus settles deeply into the economy and profoundly changes the anatomical elements and the fluids. The expectant doctrine leads its adherents at best, if not to desire, at least not to be afraid of, tertiary accidents, because after them, they think, a certain cure may still occur. This, I am sure, is an important error, against which we cannot protest too strongly. These tertiary forms, I believe, are often very grave; so serious that they usually indicate a profound and inveterate intoxication. That the iodide of potassium modifies them very often I am willing to admit; but it does not do so always. It is sometimes entirely impotent, and is useless to prevent relapses. Then, even when it does act, it does not always remove the ravages of syphilis. Here I would cite particularly those cases in which ulcerated gummata have produced, in the process of healing, contractions, perforations, atrophies, anchyloses, deforming scars, etc. Once formed, all these various lesions are permanent and incurable, or at least necessitate plastic operations, the resulting success of which is very uncertain.

Potassium iodide, then, does not always succeed in curing the tertiary manifestations of syphilis. Sometimes it will not act at all, and at other times it will not be well tolerated. In some we can get only a passing amelioration, and these cases are at least as large in number as those in which it gives cures which seem to be durable. All authors give cases in which the iodide of potassium succeeded only after the temporary administration of mercury. For my own part, I have frequently remarked that herpetic patients are unfavorably affected by the iodide.

The treatment of syphilis must be long and patiently followed, because it is a disease of long duration. Its cure takes about two years. I do not wish to be understood as saying by this that the treatment must be given constantly and without interruption during two consecutive years. It should at first be rigorously followed for about four months; it may then be suspended during a month, and again taken up for periods of three or four weeks, with interruptions of about the same period.

Syphilis, without doubt, may be cured spontaneously, but the cases seem rare, and certainly cannot be foretold. Even if the treatment is useless, it does not seem to have any serious inconveniences. Uncertainty reigns here, as it does in the whole therapeutic field; but so long as we do no harm we may act without any scruple.

Mercury remains the most powerful modifier of syphilis in its first periods. If its direct action on the virus has not been proved, it is nevertheless demonstrated

that it modifies advantageously the isolated and successive manifestations of this general disease. Being at least as efficacious as any other remedy in a case of medium intensity, it is indispensable and could not be replaced in serious and tenacious syphilides, in visceral syphilis, in that of pregnant women, and also in that of new-born children.

A woman who is suffering with syphilis rarely carries to term the product of conception. Sooner or later she aborts, or else brings into the world poor, little, miserable beings that are hardly viable. This will be continued for several years in succession unless a proper mercurial treatment be given to remove the constant cause of the miscarriages. More than one union has become fertile only after the administration of mercury to one of the parties, if not to both. These facts are well established, and it is a great error to forget them.

What other form of medication have we to combat the syphilis of the newly-born? What success can we hope for from the expectant plan? And how many of these unhappy little ones can we save by topical and other trivial medication? Let us read over again the history of those epidemics of syphilis of former centuries, or even in our own times, and see how quickly their ravages were and are arrested by the intervention of mercury!

A mercurial treatment well directed, with the help of auxiliary means taken from hygiene, regimen, and the class of tonics, is, in the majority of cases, entirely harmless. It is important, therefore, to remove the prejudice in regard to it in the minds of the public. It is rare that we cannot succeed in having mercury tolerated, thanks to the resources of modern medicine. Syphilis and mercury are both accused—and with reason—of producing poverty of blood or a sort of artificial chlorosis. This double syphilitic and mercurial anæmia is to be combated by tonics, such as iron, cinchona, good food, etc., and this should be done as a preventive, and used before the impoverishment of the blood is established. Intestinal disorders are prevented by opium and its congeners, and hydrotherapy may be prescribed, with salt-water baths or sulphur waters.

Salivation is almost impossible if the mouth is the object of careful attention by constant gargling with solutions of the chlorate of potash, and if the gums are painted from time to time with tincture of iodine.

If the usual way of administration causes intolerance, we can use mercurial inunctions. In one word, exercise therapeutic and medical art. I closed my communication to the Society, in 1867, in these words: "*The problem of the cure of syphilis without mercury is not yet solved, and nothing indicates that it will be very soon.*" I have just read over these pages, and in truth I find but little to add to what I wrote twenty years ago. Certainly even then they were not novel; but at least my words opposed precise affirmations to vague assertions, obsolete theories, and questionable principles of practice.

I might dispense with the necessity of recalling them at this date if some eccentric persons from time to time did not enter the field against mercury, and especially to accord to nature a curative power which unhappily it does not possess. But the arguments of 1867 serve to answer them just as well in 1887, and also in 1907 if they still repeat their errors. In the paper spoken of I touched upon only a small number of points in the treatment of syphilis, and if you wish to know what I think of some other questions of practice after having treated syphilis for forty years, I can formulate some propositions for you:

(*a*) In cases where the diagnosis is difficult, I never rely solely on the indications given by the iodide of potassium, but always try mercury. I have observed, at least three times, tumors of the testicle which resisted strong doses of the iodide, and in which castration seemed consequently inevitable, when, to calm my conscience, I gave mercury, which brought about a cure in a few weeks.

(*b*) I scarcely ever give iodide of potassium in large doses; two or three grammes a day are my maximum, except in a few cases of rapid evolution, such as in gumma of the nose, of the palatine arch, or the soft palate and the pharynx, where it is important to stop its ravages quickly. Here it is necessary to give as much as five to six grammes a day; but as soon as it yields I always return to the smaller doses. Onychia also requires large doses; why, I do not know.

(*c*) I am not at all a partisan of the

association of mercury and the iodide of potassium. In ordinary cases of secondary syphilis I much prefer to give the mercury alone or associated with tonics and good alimentation. However, I use the mixed treatment very willingly for the late secondary or tertiary manifestations when mercury has not been given or when it has been insufficiently administered. In such a case I prescribe simply the protiodide of mercury in doses of five centigrammes, and the iodide of potassium with it to the amount of one gramme a day. The *sirop de Gibert* is a good preparation, but it is sometimes badly tolerated. I have seen baths of corrosive sublimate perform miracles in extensive ulcerated syphilides.

(*d*) I have rarely had recourse to mercurial frictions, of which, however, I recognize the special power in certain cases where it is necessary to act quickly and energetically. Even when I advise inunctions, I always return later to the internal administration of the protiodide or of some other preparation of mercury, in small doses which are continued for a long time.

(*e*) I have never used mercurial hypodermic injections; and I only rarely see any indication for them. I have not allowed myself to be carried away with the advantages they are said to possess of being the shortest treatment, since it is pretended that a cure is certain in fifteen, twenty, or thirty days. I think, on the contrary, that the destruction or neutralization of the syphilitic virus is better assured by a slow impregnation of the economy than by its more or less sudden saturation.

(*f*) In the local treatment of primitive ulceration and precocious secondary lesions, as well as the mucous patches, I give the preference to solutions of nitrate of silver of different strengths, and also to chloral. For late secondary and tertiary ulcerations the plaster de Vigo is the best preparation. As for the ointment of iodide of potassium which is used in hyperplasias (conjunctival, glandular, or bony), it is usually badly prepared. In the strength of four parts to thirty it inflames the skin, acts as a counter-irritant, and is not absorbed; in just half this strength, on the other hand, it is well tolerated, and penetrates much better, even to the deep structures.

ORIGINAL COMMUNICATIONS.

THE PROGRESS AND LIMITATIONS OF OPERATIONS UPON THE ABDOMINAL CAVITY.*

BY J. EWING MEARS, M.D.,
Lecturer on Practical Surgery in Jefferson Medical College; Surgeon to St. Mary's Hospital.

THE surgeon of to-day, standing upon the borders of the abdominal cavity and peering into its recesses, is compelled, like Alexander of old, to express regret that no more organs exist within its domain which remain to be conquered by his art and be rendered subject to his knife. As he thus contemplates the fields of conquest, he is led to consider, In what manner were these grand victories achieved, —what the beginnings of this mighty invasion into this cavity, hitherto regarded as so well protected by its innermost barrier, which afforded not only protection against intrusion, but embraced within its folds the organs contained within, and still further opposed assault? what the development of the methods which have accomplished victory? and, finally, if any exist, what the limits of surgical procedures within this cavity?

To those acquainted, as no doubt you all are, with the history of the progress of surgery, it is not necessary to dwell in detail upon the beginnings of surgical operations upon the abdominal cavity. In truth, it may not be possible to fix, in accurate statement, the beginning. While it is no doubt true that unpremeditated operations, resulting in the successful extirpation of organs the seat of morbid changes, established the feasibility of the successful performance of such operations, and led to further inquiry and study of proper methods, yet I believe that in the Cæsarean section we find the first premeditated attempt—a well-defined plan of operation upon the cavity carried into execution, and having in view a definite purpose,—executed under the inspiration of the noble impulse to make an effort to rescue from impending death the life, happily it may be, of two beings.

To show the great progress which has been made in the performance of this operation through the Porro-Müller modifications, it is only necessary to refer to the

* The annual Address read before the Philadelphia Academy of Surgery, March 7, 1887.

results which have followed in each. For one hundred years, as stated by Dr. Clement Godson, every Cæsarean section was followed by death in the Vienna hospitals. From 1787 to 1879 the same results followed in the Maternité of Paris. In Italy it was the same. The table which he presented at the end of 1884 gave one hundred and fifty-two cases of Porro's operation, with sixty-six recoveries and eighty-six deaths, and was based upon information gathered from eleven different countries and ninety operators.

Premeditated operations upon the ovaries and uterine appendages in a state of disease may be regarded as next in order of execution, the discussion of the first of which by surgical writers began in the seventeenth century, so far as related to the effects to be accomplished by such operations. Fifty years later the possibility of performing the operations was admitted, and, with many qualifying conditions, the attempt was recommended. The continued discussion of the subject, with the gradual advancement in knowledge, led in 1809 to the successful practice of operations based upon correct diagnosis and intelligent methods of procedure.

The operation for the removal of the healthy ovaries of women—an operation greatly vaunted in these recent days, and performed, in my opinion, with the exhibition of much reckless ignorance and lack of judgment—has descended from the Middle Ages and even more remote periods, in which it was employed upon young girls for the purpose of preventing the propagation of hereditary diseases and deformities and for maintaining the supply of barren prostitutes.

With the brilliant results achieved in ovariotomy, as reflected in the gradual but positive reduction of the rate of mortality and the vastly improved methods of operation, you are all familiar.

Within a few years, morbid conditions of the Fallopian tubes have been classified, their pathological relations determined, their diagnostic symptoms defined, and their treatment by surgical procedures established. Enlargement of these organs may be cystic in character, forming as it were retention-cysts, containing simple fluid, blood, or menstrual fluid. The contents may be purulent in character, the result of specific or non-specific inflammatory action. Papillomatous or fibrous growths may be deposited in their walls, causing enlargement; and, finally, the products of conception may find lodgment within these cavities, producing the several varieties of tubal pregnancy. Of these various conditions involving the Fallopian tubes, the latter, tubal pregnancy, has for a long period attracted the attention and commanded the careful study of surgeons and obstetricians, with the result of establishing as the best and safest practice removal of the tube and its contents by abdominal section as soon as the condition has been determined by careful examination to exist.

The extirpation of solid growths of the tubes may be required in cases in which their large size gives rise to symptoms of pressure upon important structures.

Within a very recent period much attention has been bestowed upon the subject of the different forms of salpingitis,—inflammatory conditions of the tubes. In a recent communication upon the etiology, pathology, and classification of salpingitis, Dr. Sänger, of Leipsic, presented as the result of his investigations a very complete classification of this affection, based upon the theories of infection by micro-organisms. The study of diagnostic symptoms and of methods of physical exploration has led in many instances to recognition of these conditions, and justified the extirpation by abdominal section as a means of treatment. In this connection it is interesting to note that Sir Spencer Wells states, in his work issued in 1885, that he had up to that time met with but four examples in which the disease of the Fallopian tubes was sufficient to justify their removal; and, moreover, "that he had never seen anything supporting the opinion that disease of the Fallopian tubes occurs with anything approaching the extraordinary frequency with which, by some, it is alleged to occur."

Tumors of the round ligaments, fibroid in character, have been in a few instances diagnosticated and submitted to successful treatment by laparotomy.

Up to a period of twenty years ago, operations for the removal of fibroid tumors of the uterus were rarely designedly performed. As a rule, the surgeon was confronted with these growths as the result of a mistaken diagnosis, and the operation was more frequently abandoned than completed. Such operations, however,

gave knowledge and encouraged premeditated efforts, until they have become in a measure established as a justifiable surgical procedure. Unfortunately, so great has been the mortality that, at this time, some hesitation exists in the minds of surgeons with regard to its performance except in the most favorable cases.

Without doubt, many patients, the subjects of uterine myomata, are permitted to drag out a weary existence of discomfort and suffering for want of surgical interference. On the other hand, some have been hurried to an untimely end through such interference. A careful study of the results of operations, Schroeder states, leads to the conclusion "that, while ovariotomy may now be looked upon, except as regards possible advance in minute details, as a closed chapter, myomotomy, on the contrary, stands exactly in the opposite position."

Leaving the consideration of the female organs of generation contained within the pelvic cavity which have been subjected to operation by abdominal section, we pass through this gateway into the general cavity. Here we find the most brilliant achievements of modern surgery accomplished under the protecting ægis of antiseptic methods. It is quite true that some of the initial operations were performed before the era of asepsis; but they were very rare, and performed usually through errors in diagnosis.

In the order of time, operations for removal of the spleen follow those of the ovary, the first premeditated operation dating from 1826. Three conditions have been described by observers as indicating surgical interference:

1. A change in the normal position of the organ, giving rise to the movable or wandering spleen.

2. The organ in a state of hypertrophy, due usually to malarial influences, forming the ague-cake so well known in certain sections of our country.

3. Cystic degeneration, associated, as a rule, with leukæmia.

Of these varieties the first and second are most amenable to successful treatment by laparotomy, while operations in cases of the third form—the leukæmic spleen—have been followed almost universally by fatal results. The explanation of this is to be found in the condition of the blood, and not in inherent difficulties in the operation itself. Further investigations are necessary to determine the relation between leukæmia and the cystic degeneration of the spleen, in order to avoid, if possible, by preliminary constitutional treatment, the fatal results attending surgical interference.

Of thirty cases of splenectomy reported by Credé up to 1881, twenty-one died. Of the twenty-one cases sixteen were leukæmic, and in all death followed. In the nine successful cases of removal of the spleen, four were hypertrophied, two movable, two cystic, and one normal and free in an abscess of the peritoneum.

In a very able paper read before the American Surgical Association at its meeting in April, 1885, Dr. S. W. Gross reported two hundred and thirty-three cases of extirpation of the kidney, with a mortality of 44.63 per cent. Of these cases of extirpation, one hundred and eleven were by the lumbar incision, with a mortality of 36.93 per cent., and one hundred and twenty were by the ventral incision, with a mortality of 50.83 per cent. With this statement he proceeds in his paper to discuss the causes of death after nephrectomy by the two methods, presents in systematic manner the various lesions which have been treated by operation, with the percentages of mortality in each, classifies the operations, and concludes with the formulation of certain propositions for discussion based upon the analysis and careful study of the cases collated. These propositions are so complete that they may be said to present in a concise manner the rise and progress of the surgery of the kidney up to the date at which they were presented, and at the same time to furnish a guide to the performance of operations upon that organ.

Since the presentation of this paper in April, 1885, Dr. Gross has added, up to this date, one hundred and three cases to those reported at that time, and has kindly placed at my disposal the following information derived from their analysis and study. In the three hundred and thirty-four cases there were two hundred and six recoveries and one hundred and twenty-eight deaths, giving a mortality of 38.32 per cent. In one hundred and seventy-six of these cases the operation was performed by ventral incision, with ninety-five recoveries and eighty-one deaths, giving a mortality of forty-six per cent. In one

hundred and fifty-eight cases the operation was done by lumbar incision, with one hundred and eleven recoveries and forty-seven deaths, a mortality of thirty per cent. The results obtained in the one hundred and three additional cases give a decreased general mortality of 6.31 per cent.,—a decreased mortality for ventral operations of 4.83 per cent., and a decreased mortality for lumbar operations of 6.93 per cent. These results show that the death-rate has been decreased by the increased experience of the operators. He further states that the new cases add confirmatory evidence of the correctness of the conclusions stated in his paper above referred to, and which are accepted by all writers on the subject.

When it is remembered that up to twenty years ago premeditated operations upon the kidney were not considered, and that the tapping of renal cysts and abscesses was performed usually without knowledge of the organ involved until—possibly in abscess—the presence of a renal calculus disclosed the fact, and when we further reflect that up to that time all renal tumors removed by abdominal section were so done through error of diagnosis, we cannot but express surprise at the rapid development of the surgery of this organ.

The traditional dread of the results following the infliction of injury upon the peritoneum found its fullest exemplification in the treatment, in days gone by, of the liver, and thus it was always considered necessary to shut off the abdominal cavity by the formation of adhesions between the liver or gall-bladder, prior to tapping, in cases of cysts or abscesses of the former, and dropsy (when recognized) of the latter. This was done by carrying the incision to the peritoneum and packing the wound so as to excite inflammatory action. Later, tapping was performed without the danger of the passage of any of the contents of cyst or abscess into the abdomen. In abscess of the organ, especially if superficial, these adhesions are usually formed, and tapping or incision is rendered safe. In the treatment of hydatid cysts, at this day, it is regarded desirable to form adhesions between the liver and abdominal walls by packing the wound with iodoform gauze, and, if the cyst is deeply situated, dividing the hepatic tissue with the Paquelin cautery.

Wounds of the liver—punctured, lacerated, or gunshot—are chiefly dangerous by reason of the great difficulty presented in controlling hemorrhage in parenchymatous tissues. Abdominal section may in such cases be performed, catgut sutures introduced, and the Paquelin cautery or the aseptic tampon of iodoform gauze used, as advised by Dr. N. Senn. In cases of extensive subcutaneous lacerations or rupture of the liver, it occurs to me to suggest that temporary compression of the hepatic artery and portal vein, by means of long-handled padded forceps carried through the abdominal wound, may be of service in controlling hemorrhage.

Operations upon the gall-bladder had their beginning through errors in diagnosis, the distended sac being mistaken for an abscess or cyst of the liver, and being opened by tapping and incision. Some of these operations were reported as early as 1733, in which gall-stones were removed through the fistulæ. In 1867, Dr. John S. Bobbs, the brother-in-law of the distinguished Simon Cameron, of this State, performed an exploratory laparotomy, opened a distended gall-bladder, removed fifty gall-stones, sutured the incision in the sac, and closed the abdominal wound. The operation was followed by recovery of the patient,—the first operation in which cholestotomy was performed without the formation of a biliary fistula. In 1878, Dr. Marion Sims, then residing in London, performed likewise an exploratory laparotomy, incised a distended gall-bladder, and removed twenty-four ounces of fluid and sixty-six stones; the walls of the cyst were retrenched and attached to the abdominal wound, forming a biliary fistula. Sixteen stones were found in the gall-bladder at the autopsy, which was held nine days after the operation. Although biliary fistulæ had followed simple tapping and incision of distended gall-bladders, yet this was the first premeditated operation of the kind. The first operation performed with design was that of Kocher, of Berne, Switzerland,—cholecystotomy, with the formation of a fistula,—in 1878. Excision of the gall-bladder (cholecystectomy) was first performed by Langenbuch, of Berlin, in 1882. The formation of a new communication between the gall-bladder and the duodenum (duodeno-cholecystotomy), or between the gall-bladder and the transverse colon, as practised by Winiwarter in 1882, may be performed, as its feasibility

has been demonstrated by the operation of Winiwarter and confirmed by Dr. Gaston, of Atlanta, Georgia, through experiments upon dogs.

The indications for operations upon the gall-bladder by abdominal section have been well established.

Dr. Ohage, of St. Paul, Minnesota, reports in a recent paper (*Medical News*, February 19 and 26) fifty cases of cholecystotomy, with formation of fistulæ, up to date, with thirty-nine recoveries and eleven deaths,—a mortality of twenty-two per cent.; five cases of cholecystotomy without biliary fistulæ, three recoveries and two deaths,—a mortality of forty per cent.; and nine cases of cholecystectomy, with eight recoveries and one death,—a mortality of eleven per cent. In his tables Dr. Ohage has omitted (I do not know whether intentionally or not) the case of cholecystotomy performed by Dr. Keen and reported to this Academy about two years since, and the case of cholecystectomy performed incidentally by Dr. S. W. Gross when operating by ventral incision for extirpation of a tumor of the kidney.

It is not within the scope of this paper to discuss the question, now attracting the attention of surgeons, with regard to the relative merits of the two operations, cholecystotomy and cholecystectomy. It may be said that the decision of the question in the future will undoubtedly be influenced by the consideration of physiological relations and pathological conditions as well as by the results of operations.

Up to this period, the only pathological conditions of the pancreas which have been subjected to surgical treatment have been cysts due to obstruction of the duct. Of these a few cases have been reported,—one by Dr. Bozeman, in which a cystic tumor of the pancreas containing twenty pints of fluid was removed, abdominal section having been performed in the expectation of finding an ovarian cyst. The pedicle, an inch in length, was ligatured, and then divided. The patient made a successful recovery. Simple tapping and tapping and drainage, with suture of the cyst to the abdominal wall, have been performed in other cases with successful results. Carcinoma of the pancreas occurs possibly more frequently than cystic degeneration, and is not regarded at this time as amenable to treatment by surgical procedure, owing to the implication, as a rule, of important adjacent structures and the difficulties to be encountered in dealing with hemorrhage from the large blood-vessels which are in intimate relation with the organ. As Dr. Senn correctly states in his address in surgery delivered May, 1886, before the American Medical Association, the surgery of the pancreas belongs to the future. He, of all others, has contributed most to clear the way for this advance through the elaborate and extended experimental investigations conducted upon animals, the conclusions deduced therefrom having been presented in his very able paper read before the American Surgical Association in April, 1886.

Of all the operations performed upon the abdominal cavity, it may be correctly said that none exceed in brilliant achievements those performed upon the stomach and intestinal tract. The recital of the successful results obtained in the few reported cases of incised and gunshot wounds of the intestines treated through laparotomy is sufficient proof of this statement. In so short a period has this great advance been made that we may almost count the time by months. In contemplating this subject, who can avoid reflecting upon the great results which will follow in the treatment of gunshot wounds of the abdomen when, in the future, armies come in conflict, and to what an extent the surgical history of our late war would have been changed?

The fistula which followed the gunshot-wound of the stomach in the case of Alexis St. Martin demonstrated the feasibility of accomplishing the same result by operation, and gastrostomy has become an accepted operation in cases of stenosis of the œsophagus. Gastrotomy, or incision of the stomach, has been performed for the purpose of removing foreign bodies from the organ. Professor Loretta, of Bologna, Italy, has performed gastrotomy for the purpose of overcoming by forcible digital dilatation stenosis of both the cardiac and the pyloric orifice. Success has followed these attempts.

Perforating ulcer of the stomach has been successfully treated by excision, and gastrorectomy is advised in such cases.

The successful results achieved by Billroth in his cases of excision of the pylorus (pylorectomy) for malignant disease have proved not only the feasibility but also the justifiability of the operation, when

performed in the early stage of the disease. In cases in which pylorectomy is not possible by reason of the extent of the disease, temporary relief may be afforded by the formation of a communication between the stomach and upper portion of the duodenum or jejunum,—gastro-enterostomy.

Operations upon the duodenum and jejunum, having in view the formation of permanent fistulæ for the direct introduction of food into the intestine, have been performed, and have been justly characterized as unnecessary and unjustifiable.

Beginning with the early operations of Littré and Amussat upon the colon for obstruction (colotomy), and ending with the latest suggestion for the employment of laparotomy in treating pathological conditions of the intestines,—resection in cases of perforation due to ulceration of Peyer's patches in typhoid fever,—we find that the field of operation has expanded so as to include a number formerly regarded as beyond the resources of surgical art. These embrace, as recorded by Dr. Senn, subcutaneous laceration of the intestines, intestinal obstruction due to intussusception, to enteroliths, to non-malignant cicatricial stenosis, volvulus, torsion, internal hernia, and strangulation by cicatricial bands.

Enterectomy, or excision of a portion of the intestine, has been performed in a number of instances, with the most remarkable success, for gangrene, wounds, and other pathological conditions. Koeberle's extraordinary case, familiar to you all, in which six feet of the intestine were removed, indicates to what extent enterectomy may be successfully performed.

In passing judgment upon the suggestion of resection in intestinal perforation in typhoid fever, we must remember that many of the operations upon the abdominal cavity now regarded as legitimate and firmly established were a few years back regarded as equally impracticable, if not absurd.

To complete the list of conditions amenable to treatment by abdominal section, it is necessary to add to those stated above tumors of the omentum, tumors of the mesentery, retroperitoneal tumors, ascites, acute tubercular and chronic peritonitis by laparotomy and local treatment, typhlitis and perityphlitis, and rupture of the diaphragm with hernia.

I am not unmindful of the fact that in this somewhat disjointed paper I have given but a faint outline of the marvellous achievements accomplished in the surgery of the abdomen within the past few years. Yet I may hope that some good may follow,—that the time has not been misspent in simply calling attention to the subject. Knowledge upon this subject is daily increasing, facts are being established, and confirmatory evidence adduced. While much has been accomplished, much remains to be done. Time must be given to the more careful study of symptoms, in order that our methods of diagnosis shall be perfected. The limits of diagnostic laparotomy must be narrowed by the acquisition of diagnostic skill.

Calm judgment must take the place of blind enthusiasm in the determination of indications for operative interference, and, above all, honesty of purpose must guide the hand of the operator. The severe condemnation of the profession must be placed upon the indiscriminate performance of operations upon the genital organs of hysterical females, as well as upon the proposal to spay all insane women, so that the progress of abdominal surgery shall not be retarded or its good repute tarnished. The morbid desire for notoriety must not be gratified at the expense of suffering and confiding humanity.

The great advances in surgical art impose upon the surgeon of to-day higher duties and greater responsibilities. A few years ago he could, with undisturbed conscience and calm mind, watch with folded arms the progress to the end, of certain conditions with which to-day he must deal, not too soon, nor yet—equally, if not more important—too late, under the guidance of sound judgment, and with the knowledge which increasing experience and careful investigations have so liberally provided.

THE IRRITABLE HEART AND THE DEPRESSED HEART.

BY HENRY SALZER, M.D.,
Baltimore, Maryland.

"THE irritable heart" has been the subject of frequent contributions to medical literature since Da Costa's classical description of this condition in 1871.

The symptoms are "nervous palpitation," either alone or in combination with shortness of breath, especially on ascending stairs or climbing heights; certain neurasthenic phenomena, as dizziness, sick headache, numbness in one or more limbs, dragging or compressing pains in the region of the heart, back, hips, or legs; sleeplessness in spite of great fatigue, and such-like complaints. Certain objective signs, as rapid, irregular pulse, forcible, apparently hypertrophic apex-beat of the heart, often with slight concussion of the entire cardiac region even extending beyond the mammillary line, are accompanying symptoms. The area of heart-dulness is, however, normal, and other physical signs of cardiac disease are absent. Neither this strong apex-beat nor the pulse, varying from small and weak to hard and jerky, indicates increased heart-pressure. In fact, the pulse at the wrist is weakened, and can be made to disappear completely by raising the arm to a perpendicular position. The forcible apex-beat and the strong pulse are produced by disordered innervation of the heart and the arterial walls, causing apparently spastic contractions. Which of the nervous apparatus connected with cardiac innervation is here primarily affected, it is impossible, in the present state of knowledge, to determine.

The palpitations attending Basedow's disease, affections of the coronary arteries, or degenerative changes in the heart, are easily differentiated from those due to irritable heart, and are hence left out of consideration here.

The remaining organs of the body present nothing peculiar. The kidneys appear healthy, but secrete irregularly. At times the urine is scanty and rich in urates. Most frequently, however, the urine is profuse, pale in color, and of low specific gravity. The skin, especially about the face, neck, and shoulders, is often thickly covered with acneiform eruptions. The bodily temperature inclines to become elevated after the slightest disturbances, catarrhs, etc. Hands and feet tend to manifest sensations of heat rather than the contrary.

The following are generally specified as causes of this condition: hereditary nervous organization, exhausting diseases and hemorrhages, and anæmic conditions otherwise produced; mental and physical over-exertion. (It was in soldiers during the late civil war that Da Costa first thoroughly studied this condition.) The abuse of stimulants—alcohol, coffee, tea, and tobacco—and the influence of various poisons must also be included among the causes.

In my experience the combination of symptoms above described has been much more frequently met in young persons than after middle life. After the age of forty the irritable heart is comparatively rare, but, especially in males, a different train of symptoms present themselves which will be described below. The irritable heart is most frequent in young men from seventeen to twenty-five years of age. Here the specific causes are: in one class of cases great anxiety in the performance of duty, over-exertion of vital powers, sedentary occupation in crowded apartments, etc.; in others, ascetic repression of the natural desires and passions, masturbation, or the apprehension created by reading popular works upon the subject and the consequent anxiety with regard to connubial capacity; in others still, defiance of all the rules of health, rapid eating of large quantities of indigestible food, or drinking excessive quantities of various fluids; in many, reflex neuroses from nasal, pharyngeal, or gastric catarrhs, increased by excessive smoking of tobacco; in still others, intemperance in the use of alcoholic liquors, or venereal debaucheries; and probably in most cases a number of these causes combined are responsible for the condition described.

Young girls suffering with chlorosis, anæmia, digestive disorders, or genital disturbances may likewise present the symptoms of irritable heart.

Let these youthful individuals alter their mode of living; let the overtaxed clerk or mechanic change his occupation for one less confining or exacting, or adopt a country life; let the masturbator cease his degrading practices and become, in consequence of rational treatment and earnest encouragement, a proud husband and father; let the gourmand, the sot, and the debauchee alter their mode of living and become temperate, well-behaved, and regular in their deportment; let the chlorotic or hysterical girl be converted by a happy marriage into an assiduous housewife and fond mother,—and the phenomena of irritable heart rapidly disappear and a condi-

tion of good health is re-established. All subjective complaints now cease; the pulse becomes full, slow, and regular; the apex-beat is easily perceptible in its normal situation, and all the heart-sounds are normal; the complexion becomes fresh and rosy, a general plumpness replaces the appearance of malnutrition, and a sense of comfort and well-being takes the place of the morbid irritability of the system.

Few can maintain this condition of health, however, throughout life. Persons of vigorous constitution and active habits may be able to absorb, transform, and again get rid of an excess of solid and liquid food without injurious results; others, by habitual restraint and moderation in eating and drinking, avoid the dangers to which most persons subject themselves by overtaxing their assimilative organs and vascular system. I know a banker who keeps well nourished and in excellent health upon a daily allowance of two ounces of meat, a few spoonfuls of grits, two to three ounces of bread, and a half-pint of fluid (coffee, tea, milk, and water included). In summer a little fruit and about half a pint of fluid are added to the above allowance. This gentleman performs from twelve to fifteen hours of hard mental labor every day upon the slender fare mentioned.

Such examples of moderation or self-denial are, however, rare. The majority of those who formerly suffered from irritable heart, but who regained good health, remain in this condition only until the youthful resistance and elasticity become weakened and relaxed at the entrance into the middle period of life. At the age of forty and upward, increased cares and responsibilities, sickness, the habit of eating and drinking more than the comparatively inactive body demands, produce symptoms which at first view seem to indicate a return of the irritable heart from which the patient suffered twenty years before. The family physician is sought for, and the burden of complaints recited to him: palpitation, constriction of the chest, shortness of breath, especially on ascending stairs or heights, neurasthenic dyspepsia, dizziness, numbness in the limbs, sick headache, dragging pains in the cardiac region, the back and hips, stiffness of the back and limbs on awakening. The pulse is increased and irregular, the skin dull and more or less insensitive, yet easily irritated. But if the physician compares the present condition of his patient with that of fifteen or twenty years before, as noted in his case-records, he will become sensible of marked differences. The pulse is increased in rapidity, but, in spite of the patient's appearance of robust health, is weak, small, and compressible. The apex-beat of the heart is not at all perceptible, even in forced expiration and with the body bent forward. A slight concussion at the base is all the evidence of heart-impulse that even the most careful physical examination can elicit. The area of heart-dulness is normal and the valvular sounds pure, with the exception perhaps of a more or less pronounced accentuation of the second pulmonary sound.

In spite of the relatively small pulse, the propulsive power of the heart remains good; elevation of the arm does not affect the force of the pulse at the wrist.

The quantity of the urine is diminished relatively to the amounts of fluid ingested. The specific gravity is increased, ranging from 1025 to 1040. The urine is free from albumen and sugar, but is rich in urates and probably oxalates. The skin is dull (bilious); brownish spots are often found upon the hands, and at the lower portion of the tibia and near the ankles may be seen those rusty-colored pigmentations—from the size of a pin's head to that of a dime—to which Oertel first called attention as a sign of overfilling of the capillaries and veins of the subcutaneous connective tissue. Occasionally there is a tendency to moist eczemas, and the mucous membranes, especially the conjunctivæ, are apt to become chemotic.

The temperature is abnormally low. On awaking in the morning and before rising, the sublingual temperature, although the instrument remains in the mouth for fifteen minutes with the bulb pressed close to the root of the tongue, is frequently not above 96°, 96.5°, or 97° F. The patients are more likely to complain of cold than of heat. They are not actually sick, but constantly complain of a sense of discomfort or *malaise*.

In brief, these symptoms may be recapitulated as follows: *The apex-beat of the heart not perceptible, or perceptible only under the most favorable conditions; weak, rapid, and often irregular pulse, easily in-*

creased to one hundred or one hundred and twenty beats per minute upon the slightest exertion; difficulty of breathing, increased by slight exertion; often hyperidrosis, an abnormally low morning temperature, with dryness of the mouth and tongue. Relative decrease in quantity and high specific gravity of the urine, the characteristic pigmentations and morbid disposition of the skin, subjective complaints of a neurasthenic character, diminished sexual desire, and dragging pains and stiffness in the back and hips on awaking. To this collection of symptoms, it seems to me, the designation of *the depressed heart* may appropriately be given.

(To be continued.)

REPORT ON THE PROGRESS OF OTOLOGY.

BY CHARLES H. BURNETT, A.M., M.D.,

Professor of Otology, Philadelphia Polyclinic, etc.

DEFECTS OF HEARING IN RAILWAY-EMPLOYEES—RELATION OF SAME TO THE SAFETY OF THE TRAVELLING PUBLIC.

DR. LICHTENBERG, of Buda-Pesth, insists upon the importance of good hearing in train-hands of railroads, and he also shows that locomotive engineers and firemen are especially liable to ear-disease from the exposure incident to their work (*Archiv f. Ohrenheilk.*, Bd. xxiv., 1886). He then calls attention to the numerous acoustic signals and the few optical signals.

[This would hardly hold good in some parts of this country, where the optical signals predominate.—REP.]

Of two hundred and fifty railroad-hands examined by Lichtenberg, ninety-two (or 36.8 per cent.) were affected by some aural disease. Thirty-two cases were of a catarrhal form, three times an affection in the labyrinth was found, and thirty-six times the difficulty lay in the external auditory canal. He then referred to the statistics of railway-accidents, and maintained that, in view of the importance of acoustic signals and the frequency of their occurrence, and in view also of the numerous aural imperfections in the railway-hands, railway-accidents were not improbably directly the consequence of defective hearing in the employees.

THE EFFECTS OF PILOCARPIN UPON THE MUCOUS MEMBRANE OF THE TYMPANIC CAVITY.

W. Kosegarten, of Kiel, has found the use of pilocarpin beneficial in cases of dry catarrh of the middle ear complicated by labyrinth-affections (*Archiv f. Ohrenh.*, xxiv., 1886). The treatment must be prolonged for at least six weeks, if benefit is to be obtained, and the most successful cases have been those treated for three months. As a rule, an injection daily of about one centigramme of pilocarpin, except on every seventh day, was given in the cases treated the longest time. It was observed in cases with transparent membrana tympani, and even in one case with a large perforation in the membrane, that the injection of pilocarpin was regularly followed by intense congestion of the mucous membrane of the drum-cavity, and in some instances secretion ensued in the cavity of the tympanum. This process favors a loosening or softening of the stiff tissues and adhesions in the drum, and hence the conducting apparatus is made more vibratile. It is even claimed that exudations have been seen to become absorbed under this treatment, and the membrana tympani assume its normal color and transparency.

HEMORRHAGIC OTITIS IN BRIGHT'S DISEASE.

In the case related the aural disease was preceded by paraplegia (Dewèvre, *Lyon Médical*, October, 1886, and *Annales des Maladies de l' Oreille*, December, 1886). Intense pain was the first aural symptom. The discharge, at first red, became serosanguinolent, and then purulent; the mucous membrane of the tympanic cavity became intensely congested, the mastoid region red and œdematous, but not swollen. The patient recovered, but the hearing remained impaired. During the otorrhagia there was also epistaxis. Attention is drawn to the fact that this form of aural affection is sometimes seen in Bright's disease. Reference is made to the observations of this occurrence in Bright's disease reported by Rayer, Lecorché, and Fournier; later, by Rosenstein and Dieulafoy (Thesis of Pissot, 1878). Trautmann (1879), Auvert (Thèse de Paris, 1879), Alibert (Thèse, 1880), and Domergue (Thèse de Paris) have reported cases of similar aural complications in Bright's disease.

AURAL DISEASES IN DIABETES MELLITUS.

Schwabach observed a case of otitis media suppurativa in a diabetic patient, in whom an artificial perforation of the mastoid was entirely successful. The patient died two years later of apoplexy, after the

fistula in the mastoid had entirely healed and all aural symptoms had subsided (*Deutsche Med. Wochenschr.*, No. 52, 1885; *Archiv f. Ohrenh.*, Bd. xxiv., 1886). The opinion is expressed by Schwabach that this operation cannot be entirely rejected in the case of diabetic patients, as held by Kirchner and Kuhn, but should be attempted if it seems to offer the only chance of saving life in dangerous cases.

DETERMINATION OF IMPORTANT TOPOGRAPHIC RELATIONS IN THE TEMPORAL BONE BY THE EXTERNAL FORMS OF THE SKULL.

Dr. Otto Körner, of Frankfort-on-the-Main, has endeavored to show, from his examination of sixty skulls, that it is possible from the external configuration of the skull to determine some of the important features of its internal structure (*Archiv für Ohrenheilk.*, Bd. xxiv., p. 67, 1886). He gave the name of "cranial index" to the result obtained by dividing the distance between the root of the nose and the most prominent point in the occiput by the distance between the parietal protuberances. This index varies between 1.55 cm. in dolichocephalic crania and 1.076 cm. in brachycephalic crania. It appears, from a table of measurements, that the floor of the middle fossa of the skull in the dolichocephalic crania lies higher above the external acoustic meatus than in the brachycephalic.

In regard to the transverse sinus it is shown that in brachycephalic crania on both sides it lies, on the average, farther outward and projects farther into the mastoid process than in dolichocephalic crania. Regardless of the form of the cranium, the sinus lies, on the average, farther outward on the right than on the left side.

The thickness of the sinus-wall was equal in ten per cent., thinner on the right side in seventy-seven per cent., and thinner on the left side in thirteen per cent.

Practically, in respect to the artificial opening of the mastoid process, it follows that the smaller the cranial index the farther forward the opening in the mastoid must be made.

In adult skulls with an index of 1.30 cm. and less, the operation must be performed, if possible, in front of the line of attachment of the auricle, especially when the right antrum must be reached. In the new-born and very young children, as is well known, the transverse sinus does not lie in an exposed position.

[This also shows that it is always safe to operate as nearly as possible through the posterior wall of the external auditory canal in attempting to reach the mastoid antrum.—REP.]

SPONTANEOUS PERFORATION IN THE MASTOID PORTION OF THE TEMPORAL BONE.

Dr. Huntingdon Richards, of New York (*New York Medical Record*, December 11, 1886), has reported a singular case of "mastoid disease," terminating as indicated in the caption, in a man 26 years old. The patient took cold, and on the third day after the initial chill pain in the ear was felt. That night the ear began to discharge. He was not seen at first by Dr. Richards, but was treated by some one who diagnosticated a perforation in the membrana, and who prescribed "drops" for the ear. About two weeks after the first attack he was seen by Dr. A. H. Buck, "who found a slight prolapse of the upper wall of the external auditory canal, the membrana tympani red and swollen, but not markedly bulging, and having a small perforation." The patient complained of throbbing in his ear and intermittent otalgia. He was referred by Dr. Buck to Dr. Richards, with the advice to immediately perform paracentesis of the membrane and a Wilde's incision of the mastoid integument, "with poulticing and frequent use of the Angelo douche, as a means of obviating if possible the necessity for drilling the mastoid." This was done, but was not productive of any change in the appearance of the membrana or in the auditory canal. A discharge of thick pus continued, and a gravitation douche was substituted for the Angelo, a strong solution of boric acid was added to the water, and the canal was to be syringed every hour. Two days later the condition of the patient was unaltered, and three days still later there had been pain in the ear, relieved, however, by the douche. The canal was now found less swollen, but the discharge was still profuse; the wound over the mastoid was discharging but little. This was rubbed with the solid stick of nitrate of silver "for counter-irritation," and the membrana tympani was again freely incised. The ear then felt better, and the hearing seemed to improve a little. The douching was continued. Three days later the condition was the same, and some pain was reported; still three days later no pain in the ear, though discharge continued; the

membrana was less swollen, and the position of the perforation, which was 1.5 mm. in diameter, was diagnosticated as just back of and above the tip of the manubrium.

Four days later the wound over the mastoid had healed, and there was no redness of the integument and no increase of tenderness on pressure over this region. There had been no pain in the head, nor earache, for four days. The opening in the membrana tympani, however, seemed too small for perfect drainage or cleansing of the drum-cavity, and another thorough incision in the membrane was made, being carried from the perforation upward and backward to the periphery of the membrane. The patient at this time called attention to "a slight swelling situated back of the mastoid process, and over its point of junction with the occipital bone." This spot gave no pain, but was tender on pressure.

Two days subsequent to this discovery, it was found that the incision in the membrana tympani had healed completely and firmly. The general condition of the patient was good, and he had no pain in his head, nor earache. The swollen spot behind the ear, however, was more tender on pressure, but not painful. Careful palpation seemed to justify the suspicion that deep-seated fluctuation could be detected, but, the suspicion being not well founded, apparently, the patient was permitted to return to his work. Three days later the condition seemed unchanged. The swelling behind the ear was to be painted daily with tincture of iodine. In the course of two days the patient came complaining of "decided pain in the side of his head and in the region of the aforesaid swelling." The latter had increased in size, being now about an inch and a quarter in diameter, and palpation revealed undoubted fluctuation. Palpation, furthermore, caused pus to suddenly well out of the auditory meatus. It was found, upon inspection, that this pus came through the old hole in the centre of the drum-membrane. The abscess over the mastoid was opened, the knife passing down fully one inch through to the bone, and a fairly large quantity of blood and pus escaped. Syringing the abscess caused some of the fluid to escape from the external auditory meatus, and also occasioned severe pain in his head, but no dizziness. Continuance of hemorrhage led to stuffing the wound and abscess-cavity with lint; poultices were ordered, and douching the ear was continued.

The next day the patient complained of frontal headache and nausea. Subsequently there was some vomiting, the temperature rose to 100.2° F., and the pulse was 92; no pain in or about the ear. All the symptoms improved excepting the nausea and frontal and occipital headache, which still continued to some extent. The depth of the wound down to the bone was now half an inch, and by prolonged probing in the upper part of the wound an opening into the bone half an inch deep was found. Weak solutions of bichloride syringed through this opening in the bone escaped through the nostrils and were felt in the tympanic cavity. The hearing now improved from half an inch to nine inches for a watch, and the temperature and the pulse became lower; there was also less headache. Syringing the wound in the same way the next day did not cause fluid to pass through the nares, but the patient asserted that it was felt in the ear. Syringing increased the discomfort in his head, and the patient attributed all his headache for four days to the syringing done at the operation.

It is suggested by Dr. Richards that, considering the course and depth of the bone sinus, it may not be impossible that there was some exposure of the dura mater.

The location of the sinus in the bone seemed, by careful measurements, to have corresponded "pretty closely to the opening of the mastoid foramen leading into the lateral sinus." It is also suggested that the opening in the bone through which the syringe was inserted might have been the mastoid foramen pathologically enlarged, or a gap similarly formed in the masto-occipital suture. In any case, the cancellous tissue in this case extended very far backward.

In the course of two weeks more the mastoid wound had entirely healed, and the membrana tympani showed that it was returning to a normal condition. It was thought by Dr. Richards that "a more active and prompt treatment at the beginning of the attack probably would have saved the patient much pain, and perhaps might have cut short the pathological process which subsequently developed into such a serious condition."

(To be continued.)

TRANSLATIONS.

RESEARCHES ON THE MICRO-ORGANISMS OF THE MOUTH.—M. Vignal publishes in the *Archives de Physiologie* the first part of a memoir on the micro-organisms of the mouth. In this memoir he proposes to set forth the action which these micro-organisms may have on a series of simple alimentary substances, with the object of investigating the influence exerted by the gastric and pancreatic juices and the bile on these micro-organisms, in order to ascertain from this what becomes of them when carried by the food and saliva into the digestive tube. A great number of micro-organisms inhabit the mouth in the normal state; a still greater number may be found there accidentally introduced either by the food or by the inhaled air. M. Vignal endeavored by using a few precautions to get rid of these micro-organisms. He gathered them only in the morning, after having brushed the mouth the evening before with sterilized water, and with a brush likewise sterilized in steam at 120° C. In this way the micro-organisms which live only in the remaining alimentary substances were eliminated. To know the number that inhabit the mouth the microscope will not suffice, as, on the one hand, many of them so much resemble one another that it is difficult to recognize them by sight alone, while, on the other hand, a micro-organism may be more or less long and thick, although belonging to the same species. Hence the necessity of cultivating and isolating them, and of forming pure cultivations. This the author did.
